PREFACE.

One of the most interesting features of our time, is the great advance which has been made in the study of the various branches of Science. But a few years only has elapsed, since philosophy was confined to those who had received a collegiate education, or were engaged in the learned professions. By slow degrees, our public schools adopted the pure mathematics as a portion of their curriculum; whilst the schools, in which the masses were educated, ignored entirely the study in every form. It was even considered that a knowledge of Science, by calling too strongly on the mental powers, would unfit the youth for commercial pursuits; and the expensive character of such studies, on the other hand, limited them to those whom ample means placed beyond such considerations.

The nation owes a deep debt of gratitude to those noble pioneers of intellectual advancement, Lord Brougham and Dr. Birkbeck, who were among the first to break down the barriers which stood between the "people" and the "learned." The former, by his untiring exertions in connection with the Society for the Diffusion of Useful Knowledge, and the latter by the establishment of Mechanics' Institutes, have done immense good to the masses, and have earned the deepest gratitude of their countrymen. It was prophesied against the issue of their labours, that the masses would soon over-ride their employers, and that sedition and infidelity would become rampant in the land. How far such prophecies have been falsified has been shown by recent events, in which we have seen hundreds of thousands of our artisans suddenly plunged from prosperity to want, by circumstances beyond their control, and bearing their afflictions with an intelligent resignation unequalled in the history of mankind. There is no impropriety in alleging the cause of this noble feeling to be due, in a great measure, to the advancement of knowledge, and to the mental culture which such individuals have acquired by the means to which we have briefly alluded.

The present state of Education, the exigencies of Agriculture and Manufactures, together with a high appreciation of the pleasures and advantages of Science, have created a great demand for works devoted to the subject. At first sight, it would seem that abundant means had been afforded to supply this demand; but a little consideration will suffice to show that this idea is erroneous. Even with all the advantages of cheap literature, there scarcely yet exists a systematic arrangement by which persons, unaided by scholastic training, may hope to arrive at a competent knowledge of the numerous branches into which the study of nature is now divided. For want of personal experience, such cannot properly select for themselves those works most fitted to instruct them; and, in the attempt so to do, they often experience great disappointment, partly from technicalities, unfortunately too prevalent in our scientific expositions; and frequently, from the abstruse or obscure style in which those works are veiled. The practical man, again, has often to supply himself with many works on the same subject, in order to acquire both the theory and applications of it; hence much labour, patience, and expense are necessarily incurred, which too often end in weariness and disgust.

These difficulties are fairly grappled with, and, it is hoped, successfully mastered, in the following Work. It includes every branch of Science; from the study of matter and forces, to the widest applications of scientific research for social purposes. To the educated person, it offers a comprehensive *résumé* of all that is known in Experimental, Chemical, Mathematical, Mechanical, and Natural Science. To the artisan, it affords a complete guide to each branch of Science, rising, by plain and easy steps, from the very elements to the higher branches of each department. He will equally find that, if his calling in life depend on the applications of Science, his wants will be fully satisfied. The home student may undertake its perusal, with the certainty of acquiring, without the aid of tutors, a general knowledge of each branch of philosophy. In the arrangement of each subject, the circumstances of both artisan and student have been specially borne in mind; and it is hoped that no person of ordinary intelligence, will find any difficulty in mastering any portion of the Work.

With respect to the authors of each section, it will be only requisite to remark, that they stand at the head of their several departments. Without an exception, they all occupy eminent positions in the world of Science, and have distinguished themselves as much by the diffusion as by the possession of scientific information.

It will be unnecessary for us here to give any detailed explanation of the plan of the Work. This will be found in the Introduction to Physics, which follows Lord Brougham's admirable Discourse of the Objects, Pleasures, and Advantages of Science. The arrangement of the subjects has been adopted with the view of affording a thorough, but graduating course of study, so that, as the reader progresses, he may be prepared to advance, by aid of that which he has already learned. Generally speaking, it has been assumed that the reader knows nothing of the subjects treated on; and this assumption will be highly appreciated by those who have to pursue Science under any class of difficulties.

In constructing an edifice, each stone adds both to its strength and height; but unless they be joined together by a suitable cement, the building will not itself be strong. So, in a work of this kind, unless each subject be braced with the rest, each may be individually complete, without rendering the work itself so. This duty the Editor has endeavoured to perform, by adopting the plan in which the Work is arranged, by notes of reference, explanatory remarks, &c.; and even, in some cases, by modifying the valuable contributions which he has had placed at his disposal. He feels assured that their authors, animated with him in a desire to spread knowledge, will readily pardon the liberty he has so taken, if their readers are in any way benefited by such a course. In Nature, we observe that the beauty of the landscape consists in the harmony of its outlines; so in Science, whose only object is to unfold the hidden laws of nature, a similar harmony of construction must exist, if we would successfully impress its students with a sense of its beauties and perfections. Its divisions must be numerous, owing to the imperfections of human intellect; yet all these have one origin, tend to one end, and are in unison in their great design.

J. W.

INTRODUCTORY DISCOURSE

OF THE

OBJECTS, PLEASURES, AND ADVANTAGES

OF

SCIENCE.

BY HENRY LORD BROUGHAM,

D.C.L., L.L.D., F.R.S.

Member of the National Institute of France, and of the Royal Academy of Naples.

INTRODUCTORY DISCOURSE

OF THE

OBJECTS, PLEASURES, AND ADVANTAGES

OF

SCIENCE.

In order fully to understand the advantages and the pleasures which are derived from an acquaintance with any Science, it is necessary to become acquainted with that Science; and it would therefore be impossible to convey a complete knowledge of the benefits conferred by a study of the various Sciences which have hitherto been cultivated by philosophers, without teaching all the branches of them. But a very distinct idea may be given of those benefits, by explaining the nature and objects of the different Sciences: it may be shown, by examples, how much use and gratification there is in learning a part of any one branch of knowledge; and it may thence be inferred, how great reason there is to learn the whole.

It may easily be demonstrated, that there is an advantage in learning, both for the usefulness and the pleasure of it. There is something positively agreeable to all men, to all at least whose nature is not most grovelling and base, in gaining knowledge for its own sake. When you see anything for the first time, you at once derive some gratification from the sight being new; your attention is awakened, and you desire to know more about it. If it be a piece of workmanship, as an instrument, a machine of any kind, you wish to know how it is made; how it works; and what use it is of. If it be an animal, you desire to know where it comes from; how it lives; what are its dispositions, and, generally, its nature and habits. You feel this desire, too, without at all considering that the machine or the animal may ever be of the least use to yourself practically; for, in all probability, you may never see them again. But you have a curiosity to learn all about them, because they are new and unknown. You accordingly make inquiries; you feel a gratification in getting answers to your questions, that is, in receiving information, and in knowing more,—in being better informed than you were before. If you happen again to see the same instrument or animal, you find it agreeable to recollect having seen it formerly, and to think that you know something about it. If you see another instrument or animal, in some respects like, but differing in other particulars, you find it pleasing to compare them together, and to note in what they agree, and in what they differ. Now, all this kind of gratification is of a pure and disinterested nature, and has no reference to any of the common purposes of life; yet it is a pleasure—an enjoyment. You are nothing the richer for it; you do not gratify your palate or any other bodily appetite, and yet it is so pleasing, that you would give something out of your pocket to obtain it, and would forego some bodily enjoyment for its sake. The pleasure derived from Science is exactly of the like nature, or, rather, it is the very same. For what has just been spoken of is, in fact, Science, which in its most comprehensive sense, only means *Knowledge*, and in its ordinary sense means *Knowledge reduced to a System;* that is, arranged in a regular order, so as to be conveniently taught, easily remembered, and readily applied.

The practical uses of any science or branch of knowledge, are undoubtedly of the highest importance; and there is hardly any man who may not gain some positive advantage in his worldly wealth and comforts, by increasing his stock of information. But there is also a pleasure in seeing the uses to which knowledge may be applied, wholly independent of the share we ourselves may have in those practical benefits. It is pleasing to examine the nature of a new instrument, or the habits of an unknown animal, without considering whether or not they may ever be of use to ourselves or to anybody. It is another gratification to extend our inquiries, and find that the instrument or animal is useful to man, even although we have no chance of ever benefiting by the information: as, to find that the natives of some distant country employ the animal in travelling;—nay, though we have no desire of benefiting by the knowledge; as, for example, to find that the instrument is useful in performing some dangerous surgical operation. The mere gratification of curiosity; the knowing more to-day than we knew yesterday; the understanding clearly what before seemed obscure and puzzling; the contemplation of general truths, and the comparing together of different things,—is an agreeable occupation of the mind; and, beside the present enjoyment, elevates the faculties above low pursuits, purifies and refines the passions, and helps our reason to assuage their violence.

It is very true, that the fundamental lessons of philosophy may to many, at first sight, wear a forbidding aspect, because to comprehend them requires an effort of the mind somewhat, though certainly not much, greater than is wanted for understanding more ordinary matters; and the most important branches of philosophy, those which are of the most general application, are for that very reason the less easily followed, and the less entertaining when apprehended, presenting as they do, few particulars or individual objects to the mind. In discoursing of them, moreover, no figures will be at present used to assist the imagination; the appeal is made to reason, without help from the senses. But be not, therefore, prejudiced against the doctrine, that the pleasure of learning the truths which philosophy unfolds is truly above all price. Lend but a patient attention to the principles explained, and giving us credit for stating nothing which has not some practical use belonging to it, or some important doctrine connected with it, you will soon perceive the value of the lessons you are learning, and begin to interest yourselves in comprehending and recollecting them; you will find that you have actually learnt something of science, while merely engaged in seeing what its end and purpose is; you will be enabled to calculate for yourselves, how far it is worth the trouble of acquiring, by examining samples of it; you will, as it were, taste a little, to try whether or not you relish it, and ought to seek after more; you will enable yourselves to go on, and enlarge your stock of it; and after having first mastered a very little, you will proceed so far, as to look back with wonder at the distance you have reached beyond your earliest acquirements.

The Sciences may be divided into three great classes: those which relate to *Number and Quantity*—those which relate to *Matter*—and those which relate to *Mind*. The first are called the *Mathematics*, and teach the property of numbers and of figures; the second are called *Natural Philosophy*, and teach the properties of the various bodies which we are acquainted with by means of our senses; the third are called *Intellectual* or *Moral Philosophy*, and teach the nature of the mind, of the existence of which we have the most perfect evidence in our own reflections; or, in other words, they teach the moral nature of man, both as an individual, and as a member of society. Connected with all the sciences, and subservient to them, though not one of their number, is *History*, or the record of facts relating to all kinds of knowledge.

I. Mathematical Science.

The two great branches of the *Mathematics*, or the two mathematical sciences, are *Arithmetic*, the science of number, from the Greek word signifying *number*, and *Geometry*, the science of figure, from the Greek words signifying *measure of the earth*,—land-measuring having first turned men's attention to it.

When we say that 2 and 2 make 4, we state an arithmetical proposition, very simple indeed, but connected with many others of a more difficult and complicated kind. Thus, it is another proposition, somewhat less simple, but still very obvious, that 5 multiplied by 10, and divided by 2, is equal to, or makes the same number with, 100 divided by 4—both results being equal to 25. So, to find how many farthings there are in 1.000*l*., and how many minutes in a year, are questions of arithmetic which we learn to work by being taught the principles of the science one after another, or, as they are commonly called, the *rules* of addition, subtraction, multiplication, and division. Arithmetic may be said to be the most simple, though among the most useful of the sciences; but it teaches only the properties of particular and known numbers, and it only enables us to add, subtract, multiply, and divide those numbers. But suppose we wish to add, subtract, multiply, or divide numbers which we have not yet ascertained, and in all respects to deal with them as if they were known, for the purpose of arriving at certain conclusions respecting them, and, among other things, of discovering what they are; or, suppose we would examine properties belonging to all numbers; this must be performed by a peculiar kind of arithmetic, called *Universal* arithmetic, or *Algebra*.* The common arithmetic, you will presently perceive, carries the seeds of this most important science in its bosom. Thus, suppose we inquire what is the number which multiplied by 5 makes 10? This is found if we divide 10 by 5,—it is 2: but suppose that, before finding this number 2, and before knowing what it is, we would add it, whatever it may turn out, to some other number; this can only be done by putting some mark, such as a letter of the alphabet, to stand for the unknown number, and adding that letter as if it were a known number. Thus, suppose we want to find two numbers which, added together, make 9, and, multiplied by one another, make 20. There are many which, added together, make 9; as 1 and 8; 2 and 7; 3 and 6; and so on. We have, therefore, occasion to use the second condition, that multiplied by one another they should make 20, and to work upon this condition before we have discovered the particular numbers. We must, therefore, suppose the numbers to be found, and put letters for them, and by reasoning upon those letters, according to both the two conditions of adding and multiplying, we find what they must each of them be in figures, in order to fulfil or answer the conditions. Algebra teaches the rules for conducting this reasoning, and obtaining this result successfully; and by means of it we are enabled to find out numbers which are unknown, and of which we only know that they stand in certain relations to known numbers, or to one another. The instance now taken is an easy one; and you could, by considering the question a little, answer it readily enough; that is, by trying different numbers, and seeing which suited the conditions; for you plainly see that 5 and 4 are the two numbers sought; but you see this by no certain or general rule applicable to all cases, and therefore you could never work more difficult questions in the same way; and even questions of a moderate degree of difficulty would take an endless number of trials or guesses to answer. Thus a shepherd sold his flock for 80*l.*; and if he had sold four sheep more for the same money, he would have received one pound less for each sheep. To find out from this, how many the flock consisted of, is a very easy question in algebra, but would require a vast many guesses, and a long time to hit upon by common arithmetic.[*] And questions infinitely more difficult can easily be solved by the rules of algebra. In like manner, by arithmetic you can tell the properties of particular numbers; as, for instance, that the number 348 is divided by 3 exactly, so as to leave nothing over: but algebra teaches us that it is only one of an infinite variety of numbers, all divisible by 3, and any one of which you can tell the moment you see it; for they all have the remarkable property, that if you add together the figures they consist of, the sum total is divisible by 3. You can easily perceive this in any one case, as in the number mentioned, for 3 added to 4 and that to 8 make 15, which is plainly divisible by 3; and if you divide 348 by 3, you find the quotient to be 116, with nothing over. But this does not at all prove that any other number, the sum of whose figures is divisible by 3, will itself also be found divisible by 3, as 741; for you must actually perform the division here, and in every other case, before you can know that it leaves nothing over. Algebra, on the contrary, both enables you to discover such general properties, and to prove them in all their generality.[†]

---

* Algebra, from the Arabic words signifying the *reduction of fractions*; the Arabs having brought the knowledge of it into Europe.

By means of this science, and its various applications, the most extraordinary calculations may be performed. We shall give, as an example, the method of *Logarithms*, which proceeds upon this principle. Take a set of numbers going on by equal differences; that is to say, the third being as much greater than the second, as the second is greater than the first, and the common difference being the number you begin with; thus, 1, 2, 3, 4, 5, 6, and so on, in which the common difference is 1: then take another set of numbers, such that each is equal to twice or three times the one before it, or any number of times the one before it, but the common multiplier being the number you begin with: thus, 2, 4, 8, 16, 32, 64, 128; write this second set of numbers under the first, or side by side, so that the numbers shall stand opposite to one another, thus,

1	2	3	4	5	6	7
2	4	8	16	32	64	128

you will find, that if you add together any two of the upper or first set, and go to the number opposite their sum, in the lower or second set, you will have in this last set the number arising from multiplying together the numbers of the lower set corresponding or opposite to the numbers added together. Thus, add 2 to 4, you have 6 in the upper set, opposite to which in the lower set is 64, and multiplying the numbers 4 and 16 opposite to 2 and 4, the product is 64. In like manner, if you subtract one of the upper numbers from another, and opposite to their difference in the upper line, you look to the lower number, it is the quotient found from dividing one of the lower numbers by the other opposite the subtracted ones. Thus, take 4 from 6 and 2 remains, opposite to which you have in the lower line 4; and if you divide 64, the number opposite to 6, by 16, the number opposite to 4, the quotient is 4. The upper set are called the *logarithms*, of the lower set, which are called *natural numbers;* and tables may, with a little trouble, be constructed, giving the logarithms of all numbers from 1 to 10,000 and more: so that, instead of multiplying or dividing one number by another, you have only to add or subtract their logarithms, and then you at once find the product or the quotient in the tables. These are made applicable to numbers far higher than any actually in them, by a very simple process: so that you may at once perceive the prodigious saving of time and labour which is thus made. If you had, for instance, to multiply 7,543,283 by itself, and that product again by the original number, you would have to multiply a number of 7 places of figures by an equally large number, and then a number of 14 places of figures by one of 7 places, till at last you had a product of 21 places of figures—a very tedious operation; but, working by logarithms, you would only have to take three times the logarithm of the original number, and that gives the logarithm of the last product of 21 places of figures, without any further multiplication. So much for the time and trouble saved, which is still greater in questions of division; but by means of logarithms many questions can be worked, and of the most important kind, which no time or labour would otherwise enable us to resolve.

Geometry teaches the properties of figure, or particular portions of space, and distances of points from each other. Thus, when you see a triangle, or three-sided figure, one of whose sides is perpendicular to another side, you find, by means of geometrical reasoning respecting this kind of triangle, that if squares be drawn on its three sides, the large square upon the slanting side opposite the two perpendiculars, is exactly equal to the smaller squares upon the perpendiculars, taken together; and this is absolutely true, whatever be the size of the triangle, or the proportions of its sides to each other. Therefore, you can always find the length of any one of the three sides by knowing the lengths of the other two. Suppose one perpendicular side to be 3 feet long, the other 4, and you want to know the length of the third side opposite to the perpendicular; you have only to find a number such, that if, multiplied by itself, it shall be equal to 3 times 3, together with 4 times 4, that is 25.* (This number is 5.)

---

[*] It is 16.

[†] Another class of numbers divisible by 3 is discovered in like manner by algebra. Every number of 3 places, the figures (or digits) composing which are in arithmetical progression, (or rise above each other by equal differences,) is divisible by 3: as 123, 789, 357, 159, and so on. The same is true of numbers of any amount of places, provided they are composed of 3, 6, 9, &c., numbers rising above each other by equal differences, as 289, 299, 309, or 148, 214, 280, or 307142085345648276198756, which number of 24 places is divisible by 3, being composed of 6 numbers in a series whose common difference is 1137. This property, too, is only a particular case of a much more general one.

Now only observe the great advantage of knowing this property of the triangle, or of perpendicular lines. If you want to measure a line passing over ground which you cannot reach—to know, for instance, the length of one side, covered with water, of a field, or the distance of one point on a lake or bay from another point on the opposite side—you can easily find it by measuring two lines perpendicular to one another on the dry land, and running through the two points; for the line wished to be measured, and which runs through the water, is the third side of a perpendicular-sided triangle, the other two sides of which are ascertained. But there are other properties of triangles, which enable us to know the length of two sides of any triangle, whether it has perpendicular sides or not, by measuring one side, and also measuring the inclinations of the other two sides to this side, or what is called the two *angles* made by those sides with the measured side. Therefore you can easily find the perpendicular line drawn, or supposed to be drawn, from the top of a mountain through it to the bottom, that is, the height of the mountain; for you can measure a line on level ground, and also the inclination of two lines, supposing them drawn in the air, and reaching from the two ends of the measured line to the mountain's top; and having thus found the length of the one of those lines next the mountain, and its inclination to the ground, you can at once find the perpendicular, though you cannot possibly get near it. In the same way, by measuring lines and angles on the ground, and near, you can find the length of lines at a great distance, and which you cannot approach: for instance, the length and breadth of a field on the opposite side of a lake or sea; the distance of two islands; or the space between the tops of two mountains.

Again, there are *curve-lined* figures as well as straight, and geometry teaches the properties of these also. The best known of all the curves is the *circle*, or a figure made by drawing a string round one end which is fixed, and marking where its other end traces, so that every part of the circle is equally distant from the fixed point or centre. From this fundamental property, an infinite variety of others follow by steps of reasoning more or less numerous, but all necessarily arising one out of another. To give an instance; it is proved by geometrical reasoning, that if from the two ends of any diameter of the circle you draw two lines to meet in any one point of the circle whatever, those lines are perpendicular to each other.

Another property, and a most useful one, is, that the sizes, or areas, of all circles whatever, from the greatest to the smallest, from the sun to a watch-dialplate, are in exact proportion to the squares of their distances from the centre; that is, the squares of the strings they are drawn with: so that if you draw a circle with a string 5 feet long, and another with a string 10 feet long, the large circle is four times the size of the small one, as far as the space or area inclosed is concerned; the square of 10 or 100 being four times the square of 5 or 25. But it is also true, that the lengths of the circumferences themselves, the number of feet over which the ends of the strings move, are in proportion to the lengths of the strings; so that the curve of the large circle is only twice the length of the curve of the lesser.

But the circle is only one of an infinite variety of curves, all having a regular formation and fixed properties. The *oval* or *ellipse* is, perhaps, next to the circle, the most familiar to us, although we more frequently see another curve, the line formed by the motion of bodies thrown forward. When you drop a stone, or throw it straight up, it goes in a straight line; when you throw it forward, it goes in a curve line till it reaches the ground; as you see by the figure in which water runs when forced out of a pump, or from a fire-pipe, or from the spout of a kettle or teapot. The line it moves in is called a *parabola;* every point of which bears a certain fixed relation to a certain point within it, as the circle does to its centre. Geometry teaches various properties of this curve: for example, if the direction in which the stone is thrown, or the bullet fired, or the water spouted, be half the perpendicular to the ground, that is, half way between being level with the ground and being upright, the curve will come to the ground at a greater distance than if any other direction whatever were given, with the same force. So that, to make the gun carry farthest, or the fire-pipe play to the greatest distance, they must be pointed, not, as you might suppose, level or point blank, but about half way between that direction and the perpendicular. If the air did not resist, and so somewhat disturb the calculation, the direction to give the longest range ought to be exactly half perpendicular.

The *oval*, or *ellipse*, is drawn by taking a string of any certain length, and fixing, not one end as in drawing the circle, but both ends to different points, and then carrying a point round inside the string, always keeping it stretched as far as possible. It is plain, that this figure is as regularly drawn as the circle, though it is very different from it; and you perceive that every point of its curve must be so placed that the straight lines drawn from it to the two points where the string was fixed, are, when added together, always the same; for they make together the length of the string.

---

* It is a property of numbers, that every number whatever, whose last place is either 5 or 0, is, when multiplied into itself, equal to two others which are square numbers, and divisible by 3 and 4 respectively:—thus, 45×45=2025=729+1296, the squares of 27 and 36; and 60×60=3600=1296+2304, the squares of 36 and 48.

Among various properties belonging to this curve, in relation to the straight lines drawn within it, is one which gives rise to the construction of the *trammels*, or elliptic compasses, used for making figures and ornaments of this form; and also to the construction of lathes for turning oval frames, and the like.

If you wish at once to see these three curves, take a pointed sugarloaf, and cut it anywhere clean through in a direction parallel to its base or bottom; the outline or edge of the loaf where it is cut will be a *circle*. If the cut is made so as to slant, and not be parallel to the base of the loaf, the outline is an *ellipse*, provided the cut goes quite through the sides of the loaf all round, or is in such a direction that it would pass through the sides of the loaf were they extended; but if it goes slanting and parallel to the line of the loaf's side, the outline is a *parabola;* and if you cut in any direction, not through the sides all round, but through the sides and base, and not parallel to the line of the side, being nearer the perpendicular, the outline will be another curve of which we have not yet spoken, but which is called an *hyperbola*. You will see another instance of it, if you take two plates of glass, and lay them on one another; then put their edge in water, holding them upright and pressing them together; the water, which, to make it more plain, you may colour with a few drops of ink or strong tea, rises to a certain height, and its outline is this curve; which, however much it may seem to differ in form from a circle or ellipse, is found by mathematicians to resemble them very closely in many of its most remarkable properties.

These are the curve lines best known and most frequently discussed; but there are an infinite number of others all related to straight lines and other curve lines by certain fixed rules: for example, the course which any point in the circumference of a circle, as a nail in the felly of a wheel rolling along, takes through the air, is a curve called the *cycloid*, which has many remarkable properties; and, among others, this, that it is, of all lines possible, the one in which any body, not falling perpendicularly, will descend from one point to another the most quickly. Another curve often seen is that in which a rope or chain hangs when supported at both ends: it is called the *Catenary*, from the Latin for chain; and in this form some arches are built. The form of a sail filled with wind is the same curve.

II. Difference between Mathematical and Physical Truths.

You perceive, if you reflect a little, that the science which we have been considering, in both its branches, has nothing to do with matter; that is to say, it does not at all depend upon the properties or even upon the existence of any bodies or substances whatever. The distance of one point or place from another is a straight line; and whatever is proved to be true respecting this line, as, for instance, its proportion to other lines of the same kind, and its inclination towards them, what we call the *angles* it makes with them, would be equally true whether there were anything in those places, at those two points, or not. So if you find the number of yards in a square field, by measuring one side, 100 yards, and then, multiplying that by itself, which makes the whole area 10,000 square yards, this is equally true whatever the field is, whether corn, or grass, or rock, or water; it is equally true if the solid part, the earth or water, be removed, for then it will be a field of air bounded by four walls or hedges; but suppose the walls or hedges were removed, and a mark only left at each corner, still it would be true that the space inclosed or bounded by the lines supposed to be drawn between the four marks, was 10,000 square yards in size. But the marks need not be there; you only want them while measuring one side: if they were gone, it would be equally true that the lines, supposed to be drawn from the places where the marks had been, inclose 10,000 square yards of air. But if there were no air, and consequently a mere void, or empty space, it would be equally true that this space is of the size you had found it to be by measuring the distance of one point from another, of one of the space's corners or angles from another, and then multiplying that distance by itself. In the same way it would be true, that, if the space were circular, its size, compared with another circular space of half its diameter, would be four times larger: of one-third its diameter nine times larger, and of one-fourth sixteen times, and so on always in proportion to the squares of the diameters; and that the length of the circumference, the number of feet or yards in the line round the surface, would be twice the length of a circle whose diameter was one-half, thrice the circumference of one whose diameter was one-third, four times the circumference of one whose diameter was one-fourth, and so on, in the simple proportion of the diameters. Therefore, every property which is proved to belong to figures belongs to them without the smallest relation to bodies or matter of any kind, although we are accustomed only to see figures in connection with bodies; but all those properties would be equally true if no such thing as matter or bodies existed; and the same may be said of the properties of number, the other great branch of the mathematics. When we speak of twice two, and say it makes four, we affirm this without thinking of two horses, or two balls, or two trees; but we assert it concerning two of any thing and every thing equally

Nay, this branch of mathematics may be said to apply still more extensively than even the other; for it has no relation to space, which geometry has; and, therefore, it is applicable to cases where figure and size are wholly out of the question. Thus you can speak of two dreams, or two ideas, or two minds, and can calculate respecting them just as you would respecting so many bodies; and the properties you find belonging to numbers, will belong to those numbers when applied to things that have no outward or visible or perceivable existence, and cannot even be said to be in any particular place, just as much as the same numbers applied to actual bodies which may be seen and touched.

It is quite otherwise with the science which we are now going to consider, *Natural Philosophy*. This teaches the nature and properties of actually existing substances, their motions, their connections with each other, and their influence on one another. It is sometimes also called *Physics*, from the Greek word signifying *Nature*, though that word is more frequently, in common speech, confined to one particular branch of the science, that which treats of the bodily health.

We have mentioned one distinction between Mathematics and Natural Philosophy, that the former does not depend on the nature and existence of bodies, which the latter entirely does. Another distinction, and one closely connected with this, is, that the truths which Mathematics teach are *necessarily* such,—they are truths of themselves, and wholly independent of facts and experiments,—they depend only upon reasoning; and it is utterly impossible they should be otherwise than true. This is the case with all the properties which we find belong to numbers and to figures—2 and 2 must of *necessity*, and through all time, and in every place, be equal to 4: those numbers must *necessarily* be always divisible by 3, without leaving any remainder over, which have the sums of the figures they consist of divisible by 3; and circles must *necessarily*, and for ever and ever, be to one another in the exact proportion of the squares of their diameters. It cannot be otherwise; we cannot conceive it in our minds to be otherwise. No man can in his own mind suppose to himself that 2 and 2 should ever be more or less than 4; it would be an utter impossibility—a contradiction in the very ideas; and if stated in words, those words would have no sense. The other properties of number, though not so plain at first sight as this, are proved to be true by reasoning, every one step of which follows from the step immediately before, as a matter of course, and so clearly and unavoidably, that it cannot be supposed, or even imagined, to be otherwise; the mind has no means of fancying how it could be otherwise: the final conclusion, from all the steps of the reasoning or demonstration, as it is called, follows in the same way from the last of the steps, and is therefore just as evidently and necessarily true as the first step, which is always something self-evident; for instance, that 2 and 2 make 4, or that the whole is greater than any of its parts, but equal to all its parts put together. It is through this kind of reasoning, step by step, from the most plain and evident things, that we arrive at the knowledge of other things which seem at first not true, or at least not generally true; but when we do arrive at them, we perceive that they are just as true, and for the same reasons, as the first and most obvious matters; that their truth is absolute and necessary, and that it would be as absurd and self-contradictory to suppose they ever could, under any circumstances, be not true, as to suppose that 2 added to 2 could ever make 3, or 5, or 100, or anything but 4; or, which is the same thing, that 4 should ever be equal to 3, or 5, or 100, or anything but 4. To find out these reasonings, to pursue them to their consequences, and thereby to discover the truths which are not immediately evident, is what science teaches us: but when the truth is once discovered, it is as certain and plain by the reasoning, as the first truths themselves from which all the reasoning takes its rise, on which it all depends, and which require no proof, because they are self-evident at once, and must be assented to the instant they are understood.

But it is quite different with the truths which Natural Philosophy teaches. All these depend upon matter of fact; and that is learnt by observation and experiment, and never could be discovered by reasoning at all. If a man were shut up in a room with pen, ink, and paper, he might by thinking discover any of the truths in arithmetic, algebra, or geometry; it is possible at least; there would be nothing absolutely impossible in his discovering all that is now known of these sciences; and if his memory were as good as we are supposing his judgment and conception to be, he might discover it all without pen, ink, and paper, and in a dark room. But we cannot discover a single one of the fundamental properties of matter without observing what goes on around us, and trying experiments upon the nature and motion of bodies. Thus, the man whom we have supposed shut up, could not possibly find out beyond one or two of the very first properties of matter, and those only in a very few cases; so that he could not tell if these were general properties of all matter or not. He could tell that the objects he touched in the dark were hard and resisted his touch; that they were extended and were solid: that is, that they had three dimensions, length, breadth, and thickness. He might guess that other things existed besides those he felt, and that those other things resembled what he felt in these properties; but he could know nothing for certain, and could not even conjecture much beyond this very limited number of qualities. He must remain utterly ignorant of what really exists in nature, and of what properties matter in general has. These properties, therefore, we learn by experience; they are such as we know bodies to have; they happen to have them—they are so formed by Divine Providence as to have them—but they might have been otherwise formed; the great Author of Nature might have thought fit to make all bodies different in every respect.

We see that a stone dropped from our hand falls to the ground; this is a fact which we can only know by experience; before observing it, we could not have guessed it, and it is quite *conceivable* that it should be otherwise: for instance, that when we remove our hand from the body it should stand still in the air; or fly upward, or go forward, or backward, or sideways; there is nothing at all absurd, contradictory, or inconceivable in any of these suppositions; there is nothing impossible in any of them, as there would be in supposing the stone equal to half of itself, or double of itself; or both falling down and rising upwards at once; or going to the right and to the left at one and the same time. Our only reason for not at once thinking it quite conceivable that the stone should stand still in the air, or fly upwards, is that we have never seen it do so, and have become accustomed to see it do otherwise. But for that, we should at once think it as natural that the stone should fly upwards or stand still, as that it should fall down. But no degree of reflection for any length of time could accustom us to think 2 and 2 equal to anything but 4, or to believe the whole of any thing equal to a part of itself.

After we have once, by observation or experiment, ascertained certain things to exist in fact, we may then reason upon them by means of the mathematics; that is, we may apply mathematics to our experimental philosophy, and then such reasoning becomes absolutely certain, taking the fundamental facts for granted. Thus, if we find that a stone falls in one direction when dropped, and we further observe the peculiar way in which it falls, that is, quicker and quicker every instant till it reaches the ground, we learn the rule or the proportion by which the quickness goes on increasing; and we further find, that if the same stone be pushed forward on a table, it moves in the direction of the push, till it is either stopped by something, or comes to a pause by rubbing against the table and being hindered by the air. These are facts which we learn by observing and trying, and they might all have been different if matter and motion had been otherwise constituted; but supposing them to be as they are, and as we find them, we can, by reasoning mathematically from them, find out many most curious and important truths depending upon those facts, and depending upon them not accidentally, but of necessity. For example, we can find in what course the stone will move, if, instead of being dropped to the ground, it be thrown forward: it will go in the curve already mentioned, the parabola, somewhat altered by the resistance of the air, and it will run through that curve in a peculiar way, so that there will always be a certain proportion between the time it takes and the space it moves through, and the time it would have taken, and the space it would have moved through, had it dropped from the hand in a straight line to the ground. So we can prove, in like manner, what we before stated of the relation between the distance at which it will come to the ground, and the direction it is thrown in; the distance being greatest of all when the direction is half way between the level or horizontal, and the upright or perpendicular. These are mathematical truths, derived by mathematical reasoning upon physical grounds; that is, upon matter of fact found to exist by actual observation and experiment. The result, therefore, is necessarily true, and proved to be so by reasoning only, provided we have once ascertained the facts; but taken altogether, the result depends partly on the facts learned by experiment or experience, partly on the reasoning from these facts. Thus it is found to be true by reasoning, and necessarily true, that *if* the stone fall in a certain way when unsupported, it must, when thrown forward, go in the curve called a parabola, provided there be no air to resist: this is a necessary or mathematical truth, and it cannot possibly be otherwise. But when we state the matter without any supposition,—without any "*if*,"—and say, a stone thrown forward goes in a curve called a parabola, we state a truth, partly fact, and partly drawn from reasoning on the fact; and it might be otherwise if the nature of things were different. It is called a proposition or truth in Natural Philosophy; and as it is discovered and proved by mathematical reasoning upon facts in nature, it is sometimes called a proposition or truth in the *Mixed Mathematics*, so named in contradistinction to the *Pure Mathematics*, which are employed in reasoning upon figures and numbers. The man in the dark room could never discover this truth unless he had been first informed, by those who had observed the fact, in what way the stone falls when unsupported, and moves along the table when pushed. These things he never could have found out by reasoning: they are facts, and he could only reason from them after learning them by his own experience, or taking them on the credit of other people's experience. But having once so learnt them, he could discover by reasoning merely, and with as much certainty as if he lived in daylight, and saw and felt the moving body, that the motion is parabolic, and governed by certain rules. As experiment and observation are the great sources of our knowledge of Nature, and as the judicious and careful making of experiments is the only way by which her secrets can be known, Natural and Experimental Philosophy mean one and the same thing; mathematical reasoning being applied to certain branches of it, particularly those which relate to motion and pressure.

III. NATURAL OR EXPERIMENTAL SCIENCE.

NATURAL PHILOSOPHY, in its most extensive sense, has for its province the investigation of the laws of matter; that is, the properties and the motions of matter; and it may be divided into two great branches. The first and most important (which is sometimes, on that account, called *Natural Philosophy* by way of distinction, but more properly *Mechanical Philosophy*) investigates the sensible motions of bodies. The second investigates the constitution and qualities of all bodies, and has various names, according to its different objects. It is called *Chemistry*, if it teach the properties of bodies with respect to heat, mixture with one another, weight, taste, appearance, and so forth; *Anatomy* and *Animal Physiology* (from the Greek word signifying *to speak of the nature* of any thing), if it teaches the structure and functions of living bodies, especially the human; for when it shows those of other animals, we term it *Comparative Anatomy; Medicine*, if it teaches the nature of diseases, and the means of preventing them and of restoring health; *Zoology* (from the Greek words signifying *to speak of animals*), if it teach the arrangement or classification and the habits of the different lower animals; *Botany*, (from the Greek word for *herbage*), including *Vegetable Physiology*, if it teach the arrangement or classification, the structure and habits of plants; *Mineralogy*, including *Geology* (from the Greek words meaning *to speak of the earth*), if it teach the arrangement of minerals, the structure of the masses in which they are found, and of the earth composed of those masses. The term *Natural History* is given to the three last branches taken together, but chiefly as far as they teach the classification of different things, or the observation of the resemblances and differences of the various animals, plants, and inanimate and ungrowing substances in nature.

But here we may make two general observations. The *first* is, that every such distribution of the sciences is necessarily imperfect; for one runs unavoidably into another. Thus, Chemistry shows the qualities of plants with relation to other substances, and to each other; and Botany does not overlook those same qualities, though its chief object be arrangement. So Mineralogy, though principally conversant with classifying metals and earths, yet regards also their qualities in respect of heat and mixture. So, too, Zoology, besides arranging animals, describes their structure, like Comparative Anatomy. In truth, all arrangement and classifying depends upon noting the things in which the objects agree and differ; and among those things, in which animals, plants, and minerals agree, or differ, must be considered the anatomical qualities of the one and the chemical qualities of the other. From hence, in a great measure, follows the *second* observation, namely, that the sciences mutually assist each other. We have seen how Arithmetic and Algebra aid Geometry, and how both the purely Mathematical Sciences aid Mechanical Philosophy. Mechanical Philosophy, in like manner, assists, though, in the present state of our knowledge, not very considerably, both Chemistry and Anatomy, especially the latter; and Chemistry very greatly assists both Physiology, Medicine, and all the branches of Natural History.

The first great head, then, of Natural Science, is Mechanical Philosophy; and it consists of various subdivisions, each forming a science of great importance. The most essential of these, and which is indeed fundamental, and applicable to all the rest, is called *Dynamics*, from the Greek word signifying *power* or *force*, and it teaches the laws of motion in all its varieties. The case of the stone thrown forward, which we have already mentioned more than once, is an example. Another, of a more general nature, but more difficult to trace, far more important in its consequences, and of which, indeed, the former is only one particular case, relates to the motions of all bodies, which are attracted (or influenced, or drawn) by any power towards a certain point, while they are, at the same time, driven forward, by some push given to them at first, and forcing them onwards, at the same time that they are drawn towards the point. The line in which a body moves while so drawn and so driven, depends upon the force it is pushed with, the direction it is pushed in, and the kind of power that draws it towards the point; but at present, we are chiefly to regard the latter circumstance, the attraction towards the point. If this attraction be uniform, that is, the same at all distances from the point, the body will move in a circle, if one direction be given to the forward push. The case with which we are best acquainted is when the force decreases as the squares of the distances, from the centre or point of attraction, increase; that is, when the force is four times less at twice the distance, nine times less at thrice the distance, sixteen times less at four times the distance, and so on. A force of this kind acting on the body, will make it move in an oval, a parabola, or an hyperbola, according to the amount or direction of the impulse, or forward push, originally given; and there is one proportion of that force, which, if directed perpendicularly to the line in which the central force draws the body, will make it move round in a circle, as if it were a stone tied to a string and whirled round the hand. The most usual proportions in nature, are those which determine bodies to move in an oval or ellipse, the curve described by means of a cord fixed at both ends, in the way already explained. In this case, the point of attraction, the point towards which the body is drawn, will be nearer one end of the ellipse than the other, and the time the body will take to go round, compared with the time any other body would take, moving at a different distance from the same point of attraction, but drawn towards that point with a force which bears the same proportion to the distance, will bear a certain proportion, discovered by mathematicians, to the average distances of the two bodies from the point of common attraction. If you multiply the numbers expressing the times of going round, each by itself, the products will be to one another in the proportion of the average distances multiplied each by itself, and that product again by the distance. Thus, if one body take two hours, and is five yards distant, the other, being ten yards off, will take something less than five hours and forty minutes.*

---

* This is expressed mathematically by saying, that the squares of the times are as the cubes of the distances. Mathematical language is not only the simplest and most easily understood of any, but the shortest also.

Now, this is one of the most important truths in the whole compass of science; for it does so happen that the force with which bodies fall towards the earth, or what is called their *gravity*, the power that draws or attracts them towards the earth, varies with the distance from the Earth's centre, exactly in the proportion of the squares, lessening as the distance increases: at two diameters from the Earth's centre, it is four times less than at one; at three diameters, nine times less; and so forth. It goes on lessening, but never is destroyed, even at the greatest distances to which we can reach by our observations, and there can be no doubt of its extending indefinitely beyond. But, by astronomical observations made upon the motion of the heavenly bodies, upon that of the moon for instance, it is proved that her movement is slower and quicker at different parts of her course, in the same manner as a body's motion on the earth would be slower and quicker, according to its distance from the point it was drawn towards, provided it was drawn by a force acting in the proportion to the squares of the distance, which we have frequently mentioned; and the proportion of the time to the distance is also observed to agree with the rule above referred to. Therefore, she is shown to be attracted towards the Earth by a force that varies according to the same proportion in which gravity varies; and she must consequently move in an ellipse round the Earth, which is placed in a point nearer the one end than the other of that curve. In like manner, it is shown that the Earth moves round the Sun in the same curve line, and is drawn towards the sun by a similar force; and that all the other planets in their courses, at various distances, follow the same rule, moving in ellipses, and drawn towards the Sun by the same kind of power. Three of them have moons like the Earth, only more numerous, for Jupiter has four, Saturn seven, and Herschel six, so very distant, that we cannot see them without the help of glasses; but all those moons move round their principal planets, as ours does round the Earth, in ovals or ellipses; while the planets, with their moons, move in their ovals round the Sun, like our own Earth with its moon.

But this power, which draws them all towards the sun, and regulates their path and their motion round him, and which draws the moons towards the principal planets, and regulates their motion and path round those planets, is the same with the gravity by which bodies fall towards the earth, being attracted by it. Therefore, the whole of the heavenly bodies are kept in their places, and wheel round the sun, by the same influence or power that makes a stone fall to the ground.

It is usual to call the sun, and the planets which with their moons move round him (eight in number, including Neptune, lately discovered; and besides these, are the asteroids), the *Solar System*, because they are a class of the heavenly bodies far apart from the innumerable fixed stars, and so near each other as to exert a perceptible influence on one another, and thus to be connected together.

The *Comets* belong to the same system, according to this manner of viewing the subject. They are bodies which move in elliptical paths, but far longer and narrower than the curves in which the earth and the other planets and their moons roll. Our curves are not much less round than circles; the paths of the comets are long and narrow, so as, in many places, to be more nearly straight lines than circles. They differ from the planets and their moons in another respect; they do not depend on the sun for the light they give, as our moon plainly does, being dark when the earth comes between her and the sun; and as the other planets do, those of them that are nearer the sun than we are, being dark when they come between us and him, appearing to pass across his surface. But the comets give light always of themselves, being apparently vast bodies heated red-hot by coming in their course far nearer the sun than the nearest of the planets ever do. Their motion, when near the sun, is much more rapid than that of the planets; they both approach him much nearer, retreat from him to much greater distances, and take much longer time in going round him, than any of the planets do. Yet even these comets are subject to the same great law of gravitation which regulates the motions of the planets. Their year, the time they take to revolve, is in some cases 75, in others 135, in others 300 of our years; their distance is a hundred times our distance when farthest off, and not a hundred and sixtieth of our distance when nearest the sun; their swiftest motion is above twelve times swifter than ours, although ours is a hundred and forty times swifter than a cannon-ball's; yet their path is a curve of the same kind with ours, though longer and flatter, differing in its formation only as one oval differs from another by the string you draw it with having the ends fixed at two points more distant from each other: consequently the sun, being in one of those points, is much nearer the end of the path the comet moves in, than he is near the end of our path. Their motion, too, follows the same rule, being swifter the nearer the sun: the attraction of the sun for them varies according to the squares of the distances, being four times less at twice the distance, nine times less at thrice, and so on; and the proportion between the times of revolving and the distances is exactly the same, in the case of those remote bodies, as in that of the moon and the earth. One law prevails over all, and regulates their motions as well as our own; it is the gravity of the comets towards the sun, and they, like our own earth and moon, wheel round him in boundless space, drawn by the same force, acting by the same rule, which makes a stone fall when dropped from the hand.

The more full and accurate our observations are upon those heavenly bodies, the better we find all their motions agreeing with this great doctrine; although, no doubt, many things are to be taken into the account besides the force that draws them to the different centres. Thus, while the moon is drawn by the earth, and the earth by the sun, the moon is also drawn directly by the sun; and while Jupiter is drawn by the sun, so are his moons; and both Jupiter and his moons are drawn by Saturn: nay, as this power of gravitation is quite universal, and as no body can attract or draw another without being itself drawn by that other, the earth is drawn by the moon, while the moon is drawn by the earth; and the sun is attracted by the planets which he draws towards himself. These mutual attractions give rise to many deviations from the simple line of the ellipse, and produce many irregularities in the simple calculation of the times and motions of the bodies that compose the system of the universe. But the extraordinary powers of investigation applied to the subject by the modern improvements in mathematics, have enabled us at length to reduce even the greatest of the irregularities to order and system, and to unfold one of the most wonderful truths in all sciences; namely, that by certain necessary consequence of the simple fact upon which the whole fabric rests, the proportion of the attractive force to the distances at which it operates,—all the irregularities which at first seemed to disturb the order of the system, and to make the appearances depart from the doctrine, are themselves subject to a certain fixed rule, and can never go beyond a particular point, but must begin to lessen when they have slowly reached that point, and must then lessen until they reach another point, when they begin again to increase; and so on, for ever. Nay, so perfect is the arrangement of the whole system, and so accurately does it depend upon mathematical principles, that irregularities, or rather apparent deviations, have been discovered by mathematical reasoning before astronomers had observed them, and then their existence has been ascertained by observation, and found to agree precisely with the results of calculation.* Thus, the planets move in ovals, from gravity, the power that attracts them towards the sun, combined with the original impulse they received forwards; and the disturbing forces are continually varying the course of the curves or ovals, making them bulge out in the middle, as it were, on the sides, though in a very small proportion to the whole length of the ellipse. The oval thus bulging, its breadth increases by a very small quantity yearly and daily; and after a certain large number of years, the bulging becomes as great as it ever can be: then the alteration takes a contrary direction, and the curve gradually flattens as it had bulged; till, in the same number of years which it took to bulge, it becomes as flat as it ever can be, and then it begins to bulge again, and so on for ever. And so, too, of every other disturbance and irregularity in the system: what at first appears to be some departure from the rule, when more fully examined, turns out to be only a consequence of it, or the result of a more general arrangement springing from the principle of gravitation; an arrangement of which the rule itself, and the apparent or supposed exception, both form parts.

The power of gravitation, which thus regulates the whole system of the universe, is found to rule each member or branch of it separately. Thus, it is demonstrated that the tides of the ocean are caused by the gravitation which attracts the water towards the sun and moon; and the figure both of our earth and of such of the other bodies as have a spinning motion round their axis, is determined by gravitation combined with that motion; they are all flattened towards the ends of the axis they spin upon, and bulge out towards the middle.

The great discoverer of the principle on which all these truths rest, Sir Isaac Newton, certainly by far the most extraordinary man that ever lived, concluded by reasoning upon the nature of motion and matter, that this flattening must take place in our globe: every one before his time had believed the earth to be a perfect sphere or globe, chiefly from observing the round shadow which it casts on the moon in eclipses; and it was many years after his death that the accuracy of his opinion was proved by measurements on the earth's surface, and by the different weight and attraction of bodies at the equator, where it bulges, and at the poles, where it is flattened. The improvement of telescopes has enabled us to ascertain the same fact with respect to the planets Jupiter and Saturn.

Besides unfolding the general laws which regulate the motions and figures of the heavenly bodies forming our Solar System, Astronomy consists in calculations of the places, times, and eclipses of those bodies, and their moons or *satellites* (from a Latin word signifying an *attendant*), and in observations of the Fixed Stars, which are innumerable assemblages of bodies, not moving round the Sun as our Earth and the other planets do, nor receiving the light they shine with, from his light; but shining, as the Sun and the Comets do, with a light of their own, and placed, to all appearance, immovable, at immense distances from our world, that is, from our Solar System. Each of them is probably the sun of some other system like our own, composed of planets and their moons or satellites; but so extremely distant from us, that they all are seen by us like one point of faint light, as you see two lamps placed a few inches asunder, only like one, when you view them a great way off. The number of the Fixed Stars is prodigious: even to the naked eye they are very numerous, about 3,000 being thus visible; but when the heavens are viewed through the telescope, stars become visible in numbers wholly incalculable: 2,000 are discovered in one of the small collections of a few visible stars called *Constellations*; nay, what appears to the naked eye only a light cloud, as the *Milky Way*, when viewed through the telescope, proves to be an assemblage of innumerable Fixed Stars, each of them in all likelihood a sun and a system like the rest, though at an immeasurable distance from ours.

---

* The application of mathematics to chemistry has already produced a great change in that science, and is calculated to produce still greater improvements. It may be almost certainly reckoned upon as the source of new discoveries, made by induction after the mathematical reasoning has given the suggestion. The learned reader will perceive that we allude to the beautiful doctrine of *Definite* or *Multiple Proportions*. To take an example; the probability of an oxide of arsenic being discovered is impressed upon us, by the composition of arsenious and arsenic acids, in which the oxygen is as 2 to 3; and therefore we may expect to find a compound of the same base, with the oxygen as unity. The extraordinary action of chlorine and its compounds on light,leads us to expect some further discovery respecting its composition, perhaps respecting the matter of light.

The size, and motions, and distances of the heavenly bodies are such as to exceed the power of ordinary imagination, from any comparison with the smaller things we see around us. The Earth's diameter is nearly 8,000 miles in length; but the Sun's is above 880,000 miles, and the bulk of the Sun is above 1,300,000 times greater than that of the Earth. The planet Jupiter, which looks like a mere speck, from his vast distance, is nearly 1,300 times larger than the Earth. Our distance from the Sun is above 95 millions of miles; but Jupiter is 490 millions, and Saturn 900 millions of miles distant from the Sun. The rate at which the Earth moves round the Sun is 68,000 miles an hour, or 140 times swifter than the motion of a cannon-ball; and the planet Mercury, the nearest to the Sun, moves still quicker, nearly 110,000 miles an hour. We, upon the Earth's surface, besides being carried round the Sun, move round the Earth's axis by the rotatory or spinning motion which it has; so that every 24 hours we move in this manner near 24,000 miles, besides moving round the Sun above 1,600,000 miles. These motions and distances, however, prodigious as they are, seem as nothing compared to those of the comets, one of which, when farthest from the Sun, is 11,200 millions of miles from him; and, when nearest the Sun, flies at the amazing rate of 880,000 miles an hour. Sir Isaac Newton calculated its heat at 2,000 times that of red-hot iron; and that it would take thousands of years to cool. But the distance of the Fixed Stars is yet more vast: they have been supposed to be 400,000 times farther from us than we are from the Sun, that is 38 millions of millions of miles; so that a cannon-ball would take nearly nine millions of years to reach one of them, supposing there was nothing to hinder it from pursuing its course thither. As light takes about eight minutes and a quarter to reach us from the Sun, it would be above six years in coming from one of those stars; but the calculations of later astronomers prove some stars to be so far distant, that their light must take centuries before it can reach us; so that every particle of light which enters our eyes left the star it comes from three or four hundred years ago.

Astronomers have, by means of their excellent glasses, aided by Geometry and calculations, been able to observe not only stars, planets, and their satellites, invisible to the naked eye, but to measure the height of mountains in the Moon, by observations of the shadows which those eminences cast on her surface; the angles of these shadows being taken for that purpose.

The tables, which they have by the like means been enabled to form of the heavenly motions, are of great use in navigation. By means of the eclipses of Jupiter's satellites, and by the tables of the Moon's motions, we can ascertain the position of a ship at sea; for the observation of the Sun's height at mid-day gives the *latitude* of the place; that is, its distance from the equinoctial or equator, the line passing through the middle of the Earth's surface equally distant from both poles; and these tables, with the observations of the satellites, or moons, give the distance east and west of the observatory for which the tables are calculated—called the *longitude* of the place: consequently the mariner can thus tell, nearly, in what part of the ocean he is, how far he has sailed from his port of departure, and how far he must sail, and in what direction, to gain the port of his destination. The advantage of this knowledge is therefore manifest in the common affairs of life; but it sinks into insignificance compared with the vast extent of those views which the contemplations of the science afford, of numberless worlds filling the immensity of space, and all kept in their places, and adjusted in their prodigious motions by the same simple principle, under the guidance of an all-wise and all-powerful Creator.

We have been considering the application of Dynamics to the motions of the heavenly bodies, which forms the science of *Physical Astronomy*. The application of Dynamics to the calculation, production, and direction of motion, forms the science of *Mechanics*, sometimes called *Practical Mechanics*, to distinguish it from the more general use of the word, which comprehends every thing that relates to motion and force. The fundamental principle of the science, upon which it mainly depends, flows immediately from a property of the circle already mentioned, and which, perhaps, appeared at the moment of little value,—that the lengths of circles are in proportion to their diameters. Observe how upon this simple truth nearly the whole of those contrivances are built by which the power of man is increased as far as solid matter assists him in extending it; and nearly the whole of those doctrines, too, by which he is enabled to explain the voluntary motions of animals, as far as these depend upon their own bodies. There can be nothing more instructive in showing the importance and fruitfulness of scientific truths, however trivial and forbidding they may at first sight appear. For it is an immediate consequence of this property of the circle, that if a rod of iron, or beam of wood, or any other solid material, be placed on a point, or pivot, so that it may move as the arms of a balance do round its centre, or a see-saw board does round its prop, the two ends will go through parts of circles, each proportioned to that arm of the beam to which it belongs: the two circles will be equal if the pivot be in the centre or middle point of the beam; but if it be nearer one end than the other, say three times, that end will go through a circular space, or arch, three times shorter than the circular space the other end goes through in the same time. If, then, the end of the long beam pass through three times the space, it must move with three times the swiftness of the short beam's end, since both move in the same time; and therefore any force applied to the long end must overcome the resistance of three times that force applied at the opposite end, since the two ends move in contrary directions: hence one pound placed at the long end would balance three placed at the short end. The beam we have been supposing is called a *Lever*, and the same rule must evidently hold for all proportions of the lengths of its arms. If, then, the lever be seventeen feet long, and the pivot, or *fulcrum* (as it is called, from a Latin word signifying *support*), be a foot from one end, an ounce placed on the other end will balance a pound placed on the near end; and the least additional weight, or the slightest push or pressure on the far end, so loaded, will make the pound weight on the other move upwards. If, instead of an ounce, we place upon the end of the long arm the short arm of a second beam or lever supported by a fulcrum, one foot from it, and then place the long arm of this second lever upon the short arm of a third lever, whose fulcrum is one foot from it; and if we put on the end of this third lever's long arm an ounce weight, that ounce will move upwards a pound on the second lever's long arm, and this moving upwards will cause the short arm to force downwards sixteen pounds at the long end of the first lever, which will make the short end of the first lever move upwards, though two hundred and fifty-six pounds be laid on it: the same thing continuing, a pound on the long arm of the third lever will move a ton and three-quarters on the short arm of the first lever; that is, will balance it, so that the slightest pressure with the finger, or a touch from a child's hand, will move as much as two horses can draw. The lever is called, on this account, a *mechanical power;* and there are five other mechanical powers, of most of which its properties form the foundation; indeed they have all been resolved into combinations of levers. The pulley seems the most difficult to reduce under the principle of the lever. Thus the *wheel and axle* is only a lever moving round an axle, and always retaining the effect gained during every part of the motion, by means of a rope wound round the butt end of the axle; the spoke of the wheel being the long arm of the lever, and the half diameter of the axle its short arm. By a combination of levers, wheels, pulleys, so great an increase of force is obtained, that, but for the obstruction from friction, and the resistance of the air, there could be no bounds to the effect of the smallest force thus multiplied; and to this fundamental principle Archimedes, one of the most illustrious mathematicians of ancient times, referred, when he boasted, that if he only had a pivot or fulcrum whereon he might rest his machinery, he could move the Earth. Upon so simple a truth, assisted by the aid derived from other sources, rests the whole fabric of mechanical power, whether for raising weights, or cleaving rocks, or pumping up rivers from the bowels of the earth; or, in short, performing any of those works to which human strength, even augmented by the help of the animals whom Providence has subdued to our use, would prove altogether inadequate.

The application of Dynamics to the pressure and motions of fluids, constitutes a science which receives different appellations according as the fluids are heavy and liquid like water, or light and invisible like air. In the former case it is called *Hydrodynamics*, from the Greek words signifying *water*, and *power* or *force;* in the latter *Pneumatics*, from the Greek word signifying *breath* or *air;* and Hydrodynamics is divided into *Hydrostatics*, which treats of the weight and pressure of liquids, from the Greek words for *balancing* of *water;* and *Hydraulics*, which treats of their motion, from the Greek name for certain musical instruments played with *water* in *pipes*.

The discoveries to which experiments, aided by mathematical reasoning, have led, upon the pressure and motion of fluids, are of the greatest importance, whether we regard their application to practical purposes, or to their use for explaining the appearances in nature, or their singularity as the subjects of scientific contemplation. When it is found that the pressure of water or any other liquid upon the surface that contains it, is not in the least degree proportioned to its bulk, but only to the height at which it stands, so that a long small pipe, containing a pound or two of the fluid, will give the pressure of twenty or thirty tons; nay, of twice or thrice as much, if its length be increased and its bore lessened, without the least regard to the quantity of the liquid, we are not only astonished at so extraordinary and unexpected a property of matter, but we straightway perceive one of the great agents employed in the vast operations of nature, in which the most trifling means are used to work the mightiest effects. We likewise learn to guard against many serious mischiefs in our own works, and to apply, safely and usefully, a power calculated, according as it is directed, either to produce unbounded devastation, or to render the most beneficial service

Nor are the discoveries relating to the Air less interesting in themselves, and less applicable to important uses. It is an agent, though invisible, as powerful as Water, in the operations both of nature and of art. Experiments of a simple and decisive nature show the amount of its pressure to be between 14 and 15 pounds on every square inch; but, like all other fluids, it presses equally in every direction: so that though, on the hand, there is a pressure downwards of above 250 pounds, yet this is exactly balanced by an equal pressure upwards, from the air pressing round and getting below. If, however, the air on one side be removed, the whole pressure from the other acts unbalanced. Hence the ascent of water in pumps, which suck out the air from a barrel, and allow the pressure upon the water to force it up 32 or 33 feet, that body of water being equal to the weight of the atmosphere. Hence the ascent of the mercury in the barometer is only 28 or 29 inches, mercury being between 13 and 14 times heavier than water. Hence, too, the motion of the steam-engine; the piston of which, until the direct force of steam was applied, used to be pressed downwards by the weight of the atmosphere from above, all air being removed below by filling the cylinder with steam, and then suddenly cooling and converting that steam into water, so as to leave nothing in the space it had occupied. Hence, too, the power which some animals possess of walking along the perpendicular surfaces of walls, and even the ceilings of rooms, by squeezing out the air between the inside of their feet and the wall, and thus being supported by the pressure of the air against the outside of their feet.

The science of *Optics* (from the Greek word for *seeing*), which teaches the nature of light, and of the sensation conveyed by it, presents, of itself, a field of unbounded extent and interest. To it the arts, and the other sciences, owe those most useful instruments which have enabled us at once to examine the minutest parts of the structure of animal and vegetable bodies, and to calculate the size and the motions of the most remote of the heavenly bodies. But as an object of learned curiosity, nothing can be more singular than the fundamental truth discovered by the genius of Newton,—that the light, which we call white, is in fact composed of all the colours, blended in certain proportions; unless, perhaps, it be that astonishing conjecture of his unrivalled sagacity, by which he descried the inflammable nature of the diamond, and its belonging, against all appearance of probability, to the class of oily substances, from having observed, that it stood among them, and far removed from all crystals, in the degree of its action upon light; a conjecture turned into certainty by discoveries made a century afterwards.

To a man who, for original genius and strong natural sense, is not unworthy of being named after this illustrious sage, we owe the greater part of *Electrical* science. It treats of the peculiar substance, resembling both light and heat, which, by rubbing, is found to be produced in a certain class of bodies, as glass, wax, silk, amber; and to be conveyed easily or *conducted* through others, as wood, metals, water; and it has received the name of *Electricity*, from the Greek word for *amber*. Dr. Franklin discovered that this is the same matter which, when collected in the clouds, and conveyed from them to the earth, we call *lightning*, and whose noise, in darting through the air, is *thunder*. The observation of some movements in the limbs of a dead frog gave rise to the discovery of *Voltaic Electricity*, or *Galvanism*, as it was at first called from the name of the discoverer; and which has of late years given birth to improvements that have changed the face of chemical philosophy, affording a new proof how few there are of the processes of nature incapable of repaying the labour we bestow in patiently and diligently examining them. It is to the results of the remark accidentally made upon the twitching in the frog's leg, not, however, hastily dismissed and forgotten, but treasured up and pursued through many an elaborate experiment and calculation, that we owe our acquaintance with the extraordinary metals potassium and sodium, lighter than water, and more inflammable than phosphorus, which form, when burned by mere exposure to the air, two of the salts best known in commerce, and the principal ingredients in saltpetre and common salt.

In order to explain the nature and objects of those branches of Natural Science more or less connected with the mathematics, some details were necessary, as without them it was difficult immediately to perceive their importance, and, as it were, relish the kind of instruction which they afford. But the same course need not be pursued with respect to the other branches. The value and the interest of chemistry is at once perceived, when it is known to teach the nature of all bodies; the relations of simple substances to heat and to one another, or their combinations together; the composition of those which nature produces in a compound state; and the application of the whole to the arts and manufactures. Some branches of philosophy, again, are chiefly useful and interesting to particular classes, as surgeons and physicians. Others are easily understood by a knowledge of the principles of Mechanics and Chemistry, of which they are applications and examples; as those which teach the structure of the earth and the changes it has undergone; the motions of the muscles, and the structure of the parts of animals; the qualities of animal and vegetable substances; and that department of Agriculture which treats of soils, manure, and machinery. Other branches are only collections of facts, highly curious and useful indeed, but which any one who reads or listens, perceives as clearly, and comprehends as readily, as the professed student. To this class belongs Natural History, in so far as it describes the habits of animals and plants, and its application to that department of Agriculture which treats of cattle and their management.

IV. Application of Natural Science to the Animal and Vegetable World.

But, for the purpose of further illustrating the advantages of Philosophy, its tendency to enlarge the mind, as well as to interest it agreeably, and afford pure and solid gratification, a few instances may be given of the singular truths brought to light by the application of Mathematical, Mechanical, and Chemical knowledge to the habits of animals and plants; and some examples may be added of the more ordinary and easy, but scarcely less interesting observations, made upon those habits, without the aid of the profounder sciences.

We may remember the curve line which mathematicians call a Cycloid. It is the path which any point of a circle, moving along a plane, and round its centre, traces in the air; so that the nail on the felly of a cart-wheel moves in a Cycloid, as the cart goes along, and as the wheel itself both turns round its axle and is carried along the ground. Now this curve has certain properties of a peculiar and very singular kind with respect to motion. One is, that if any body whatever move in a cycloid by its own weight or swing, together with some other force acting upon it all the while, it will go through all distances of the same curve in exactly the same time; and, accordingly, pendulums have sometimes been contrived to swing in such a manner, that they shall describe cycloids, or curves very near cycloids, and thus move in equal times, whether they go through a long or a short part of the same curve. Again, if a body is to descend from any one point to any other, not in the perpendicular, by means of some force acting on it together with its weight, the line in which it will go the quickest of all will be the cycloid; not the straight line, though that is the shortest of all lines which can be drawn between the two points; nor any other curve whatever, though many are much flatter, and therefore shorter than the cycloid—but the cycloid, which is longer than many of them, is yet, of all curved or straight lines which can be drawn, the one the body will move through in the shortest time. Suppose, again, that the body is to move from one point to another, by its weight and some other force acting together, but to go through a certain space,—as a hundred yards,—the way it must take to do this, in the shortest time possible, is by moving in a cycloid; or the length of a hundred yards must be drawn into a cycloid, and then the body will descend through the hundred yards in a shorter time than it could go the same distance in any other path whatever. Now, it is believed that Birds, as the Eagle, which build in the rocks, drop or fly down from height to height in this course. It is impossible to make very accurate observations of their flight and path; but there is a general resemblance between the course they take and the cycloid, which has led ingenious men to adopt this opinion.

If we have a certain quantity of any substance, a pound of wood, for example, and would fashion it in the shape to take the least room, we must make a globe of it; it will in this figure have the smallest surface. But suppose we want to form the pound of wood, so that in moving through the air or water it shall meet with the least possible resistance; then we must lengthen it out for ever, till it becomes not only like a long-pointed pin, but thinner and thinner, longer and longer, till it is quite a straight line, and has no perceptible breadth or thickness at all. If we would dispose of the given quantity of matter, so that it shall have a certain length only, say a foot, and a certain breadth at the thickest part, say three inches, and move through the air or water with the smallest possible resistance which a body of those dimensions can meet, then we must form it into a figure of a peculiar kind called the *Solid of least resistance*, because, of all the shapes that can be given to the body, its length and breadth remaining the same, this is the one which will make it move with the least resistance through the air, or water, or other fluid. A very difficult chain of mathematical reasoning, by means of the highest branches of algebra, leads to a knowledge of the curve which, by revolving on its axis, makes a solid of this shape, in the same way that a circle, by so revolving, makes a sphere or globe; and the curve certainly resembles closely the face or head part of a fish. Nature, therefore (by which we always mean the Divine Author of nature), has fashioned these fishes so, that, according to mathematical principles, they swim the most easily through the element they live and move in.*

Suppose upon the face part of one of these fishes a small insect were bred, endowed with faculties sufficient to reason upon its condition, and upon the motion of the fish it belonged to, but never to have discovered the whole size and shape of the face part; it would certainly complain of the form as clumsy, and fancy that it could have made the fish so as to move with less resistance. Yet if the whole shape were disclosed to it, and it could discover the principle on which that shape was preferred, it would at once perceive, not only that what had seemed clumsy was skilfully contrived, but that, if any other shape whatever had been taken, there would have been an error committed; nay, *that there must of necessity* have been an error; and that the very best possible arrangement had been adopted. So it may be with man in the universe, where, seeing only a part of the great system, he fancies there is evil; and yet, if he were permitted to survey the whole, what had seemed imperfect might appear to be necessary for the general perfection, insomuch that any other arrangement, even of that seemingly imperfect part, must needs have rendered the whole less perfect. The common objection is, that what seems evil *might have* been avoided; but in the case of the fish's shape, it *could not* have been avoided.

It is found by optical inquiries, that the particles or rays of light, in passing through transparent substances of a certain form, are bent to a point where they make an image or picture of the shining bodies they come from, or of the dark bodies they are reflected from. Thus, if a pair of spectacles be held between a candle and the wall, they make two images of the candle upon it; and if they be held between the window and a sheet of paper when the sun is shining, they make a picture on the paper of the houses, trees, fields, sky, and clouds. The eye is found to be composed of several natural magnifiers which make a picture on a membrane at the back of it, and from this membrane there goes a nerve to the brain, conveying the impression of the picture, by means of which we see. Now, white light was discovered by Newton to consist of differently-coloured parts, which are differently bent in passing through transparent substances, so that the lights of several colours come to a point at different distances, and thus create an indistinct image at any one distance. This was long found to make our telescopes imperfect, insomuch that it became necessary to make them of reflectors or mirrors, and not of magnifying glasses, the same difference not being observed to affect the reflection of light. But another discovery was, about fifty years afterwards, made by Mr. Dollond—that, by combining different kinds of glass in a compound magnifier, the difference may be greatly corrected; and on this principle he constructed his telescopes. It is found, too, that the different natural magnifiers of the eye are combined upon a principle of the same kind. Thirty years later, a third discovery was made by Mr. Blair, of the greatly superior effect which combinations of different liquids have in correcting the imperfection; and, most wonderful to think, when the eye is examined, we find it consists of different liquids, acting naturally upon the same principle which was thus recently found out in optics, by many ingenious mechanical and chemical experiments.

---

* The feathers of the wings of birds are found to be placed at the *best possible* angle for helping on the bird by their action on the air.

Again, the point to which any magnifier collects the light is more or less distant as the magnifier is flatter or rounder, so that a small globe of glass or any transparent substance makes a microscope. And this property of light depends upon the nature of lines, and is purely of a mathematical nature, after we have once ascertained by experiment, that light is bent in a certain way when it passes through transparent bodies. Now birds flying in the air, and meeting with many obstacles, as branches and leaves of trees, require to have their eyes sometimes as flat as possible for protection; but sometimes as round as possible, that they may see the small objects, flies, and other insects, which they are chasing through the air, and which they pursue with the most unerring certainty. This could only be accomplished by giving them a power of suddenly changing the form of their eyes. Accordingly, there is a set of hard scales placed on the outer coat of their eye, round the place where the light enters; and over these scales are drawn the muscles or fibres by which motion is communicated; so that, by acting with these muscles, the bird can press the scales, and squeeze the natural magnifier of the eye into a round shape when it wishes to follow an insect through the air, and can relax the scales, in order to flatten the eye again, when it would see a distant object, or move safely through leaves and twigs. This power of altering the shape of the eye is possessed by birds of prey in a very remarkable degree. They can thus see the smallest objects close to them, and can yet discern larger bodies at vast distances, as a carcass stretched upon the plain, or a dying fish afloat on the water.

A singular provision is made for keeping the surface of the bird's eye clean—for wiping the glass of the instrument, as it were—and also for protecting it, while rapidly flying through the air and through thickets, without hindering the sight. Birds are, for these purposes, furnished with a third eyelid, a fine membrane or skin, which is constantly moved very rapidly over the eyeball by two muscles placed in the back of the eye. One of the muscles ends in a loop, the other in a string which goes through the loop, and is fixed in the corner of the membrane, to pull it backward and forward. If you wish to draw a thing towards any place with the least force, you must pull directly in the line between the thing and the place; but if you wish to draw it as quickly as possible, and with the most convenience, and do not regard the loss of force, you must pull obliquely, by drawing it in two directions at once. Tie a string to a stone, and draw it straight towards you with one hand; then make a loop on another string, and running the first through it, draw one string in each hand, not towards you, but sideways, till both strings are stretched in a straight line: you will see how much more easily the stone moves quickly than it did before when pulled straight forward. Again, if you tie strings to the two ends of a rod, or slip of card, in a running groove, and bring them to meet and pass through a ring or hole, for every inch in a straight line that you draw both together below the ring, the rod will move onward two. Now this is proved, by mathematical reasoning, to be the necessary consequence of forces applied obliquely: there is a loss of power, but a great gain in velocity and convenience. This is the thing required to be gained in the third eyelid, and the contrivance is exactly that of a string and a loop, moved each by a muscle, as the two strings are by the hands in the cases we have been supposing.

A third eyelid of the same kind is found in the horse, and called the *haw;* it is moistened with a pulpy substance (or mucilage) to take hold of the dust on the eyeball, and wipe it clear off; so that the eye is hardly ever seen with anything upon it, though greatly exposed from its size and posture. The swift motion of the haw is given to it by a gristly elastic substance placed between the eyeball and the socket, and striking obliquely, so as to drive out the haw with great velocity over the eye, and then let it come back as quickly. Ignorant persons, when this haw is inflamed from cold, and swells so as to appear, which it never does in a healthy state, often mistake it for an imperfection, and cut it off: so nearly do ignorance and cruelty produce the same mischief.

If any quantity of matter, as a pound of wood or iron, be fashioned into a rod of a certain length, say one foot, the rod will be strong in proportion to its thickness; and, if the figure be the same, that thickness can only be increased by making it hollow. Therefore hollow rods or tubes, of the same length and quantity of matter, have more strength than solid ones. This is a principle so well understood now, that engineers make their axles and other parts of machinery hollow, and therefore stronger with the same weight than they would be if thinner and solid. Now the bones of animals are all more or less hollow; and are therefore stronger with the same weight and quantity of matter, than they otherwise would be. But birds have the largest bones in proportion to their weight; their bones are more hollow than those of animals which do not fly; and therefore they have the needful strength, without having to carry more weight than is absolutely necessary. Their quills derive strength from the same construction. They possess another peculiarity to help their flight. No other animals have any communication between the air-vessels of the lungs and the hollow parts of their bodies; but birds have it; and by this means they can blow out their bodies as we do a bladder, and thus become lighter when they would either make their flight towards the ground slower, or rise more swiftly, or float more easily in the air; while, by lessening their bulk and closing their wings, they can drop more speedily if they wish to chase or to escape. Fishes possess a power of the same kind, though not by the same means. They have *air-bladders* in their bodies, and can puff them out, or press them closer, at pleasure: when they want to rise in the water, they fill out the bladder, and this lightens them; when they would sink, they squeeze the bladder, pressing the air into a smaller space, and this makes them heavier. If the bladder break, the fish remains at the bottom, and can be held up only by the most laborious exertions of the fins and tail. Accordingly, flat fish, such as skaits and flounders, which have no air-bladders, seldom rise from the bottom, but are found lying on banks in the sea, or at the bottom of rivers.

If you have a certain space, as a room, to fill up with closets or little cells, all of the same size and shape, there are only three figures which will answer, and enable you to fill the room without losing any space between the cells; they must either be squares, or figures of three equal sides, or figures of six equal sides. With any other figures whatever, space would be lost between the cells. This is evident upon considering the matter; and it is proved by mathematical reasoning. The six-sided figure is by far the most convenient of those three shapes, because its corners are flatter, and any round body placed in it has therefore more space, less room being lost in the corners. This figure, too, is the strongest of the three; any pressure from without or from within will hurt it least, as it has something of the strength of an arch. A round figure would be still stronger, but then room would be lost between the circles, whereas with the six-sided figure none is lost. Now, it is a most remarkable fact, that *Bees* build their cells exactly in this shape, and thereby save both room and materials beyond what they could save if they built them in any other shape whatever. They build in the very best possible shape for their purpose, which is to save all the room and all the wax they can. So far as to the shape of the walls of each cell; but the roof and floor, or top and bottom, are built on equally true principles. It is proved by mathematicians, that, to give the greatest strength, and save the most room, the roof and floor must be made of three square planes meeting in a point; and they have further proved, by a demonstration belonging to the highest parts of Algebra, that there is one particular angle or inclination of those planes to each other where they meet, which makes a greater saving of materials and of work than any other inclination whatever could possibly do. Now, the Bees actually make the tops and bottoms of their cells of three planes meeting in a point; and the inclinations or angles at which they meet are precisely those found out by the mathematician to be the best possible for saving wax and work.* Who would dream of the bee knowing the highest branch of the Mathematics—the fruit of Newton's most wonderful discovery—a result, too, of which he was himself ignorant, one of his most celebrated followers having found it out in a later age? This little insect works with a truth and correctness which are perfect, and according to the principles at which man has arrived only after ages of slow improvement in the most difficult branch of the most difficult science. But the Mighty and All-wise Creator, who made the insect and the philosopher, bestowing reason on the latter, and giving the former to work without it—to Him all truths are known to all eternity, with an intuition that mocks even the conceptions of the sagest of human kind.

It may be recollected, that when the air is exhausted or sucked out of any vessel, there is no longer the force necessary to resist the pressure of the air on the outside; and the sides of the vessels are therefore pressed inwards with violence: a flat glass would thus be broken, unless it were very thick; a round one, having the strength of an arch, would resist better; but any soft substance, as leather or skin, would be crushed or squeezed together at once. If the air were only sucked out slowly, the squeezing would be gradual; or, if it were only half sucked out, the skin would only be partly squeezed together. This is the process by which *Bees* reach the fine dust and juices of hollow flowers, like the honeysuckle, and some kinds of long fox-glove, which are too narrow for them to enter. They fill up the mouth of the flower with their bodies, and suck out the air, or at least a large part of it; this makes the soft sides of the flower close, and squeezes the dust and juice towards the insect, as well as a hand could do, if applied to the outside.

We may remember this pressure or weight of the atmosphere as shown by the barometer and the sucking-pump. Its weight is near fifteen pounds on every square inch, so that if we could entirely squeeze out the air between our two hands, they would cling together with a force equal to the pressure of double this weight, because the air would press upon both hands; and if we could contrive to suck or squeeze out the air between one hand and the wall, the hand would stick fast to the wall, being pressed on it with the weight of above two hundredweight, that is, near fifteen pounds on every square inch of the hand. Now, by a most curious discovery made by Sir Everard Home, the distinguished anatomist, it is found that this is the very process by which *Flies* and other insects of a similar description are enabled to walk up perpendicular surfaces, however smooth, as the sides of walls, and panes of glass in windows, and to walk as easily along the ceiling of a room with their bodies downwards and their feet over head. Their feet, when examined by a microscope, are found to have flat skins or flaps, like the feet of web-footed animals, as ducks and geese; and they have, by means of strong folds, the power of drawing the flap close down upon the glass or wall the fly walks on, and thus squeezing out the air completely, so as to make a vacuum between the foot and the glass or wall. The consequence of this is, that the air presses the foot on the wall with a very considerable force compared to the weight of the fly; for if its feet are to its body in the same proportion as ours are to our bodies, since we could support by a single hand on the ceiling of the room (provided it made a vacuum) more than our whole weight, namely, a weight of above fifteen stone, the fly can easily move on four feet in the same manner by help of the vacuum made under its feet.

---

* Kœnig, pupil of Bernoulli, and Maclaurin, proved by very refined investigations, carried on with the aid of the fluxional calculus, that the obtuse angle must be 109° 28′, and the acute 70° 32′, to save the most wax and work possible. Maraldi found by actual measurement, that the angles are *about* 110° and 70°. These angles never vary in any place; and it is scarcely less singular, that the breadth of all bees' cells is everywhere precisely the same, the drone or male cells being 5-18ths, and the worker or female cells 13-60ths of an inch in breadth, and this in all countries and times.

It has likewise been found that some of the larger *Sea-animals* are, by the same construction, only upon a greater scale, enabled to climb the perpendicular and smooth surfaces of the ice hills among which they live. Some kinds of *Lizard* have a like power of climbing, and of creeping with their bodies downwards along the ceiling of a room; and the means by which they are enabled to do so are the same. In the large feet of those animals, the contrivance is easily observed, of the toes and muscles, by which the skin of the foot is pinned down, and the air excluded in the act of walking or climbing; but it is the very same, only upon a larger scale, with the mechanism of a fly's or a butterfly's foot; and both operations, the climbing of the sea-horse on the ice, and the creeping of the fly on the window or the ceiling, are performed exactly by the same power, the weight of the atmosphere, which causes the quicksilver to stand in the weather-glass, the wind to whistle through a key-hole, and the piston to descend in an old steam-engine.

Although philosophers are not agreed as to the peculiar action which light exerts upon vegetation, and there is even some doubt respecting the decomposition of air and water during that process, one thing is undeniable,—the necessity of light to the growth and health of plants: without it they have neither colour, taste, nor smell; and accordingly they are for the most part so formed as to receive it at all times when it shines on them. Their cups, and the little assemblages of their leaves before they sprout, are found to be more or less affected by the light, so as to open and receive it. In several kinds of plants this is more evident than in others; their flowers close entirely at night, and open in the day. Some constantly turn round towards the light, following the sun, as it were, while he makes or seems to make his revolution, so that they receive the greatest quantity possible of his rays. Thus clover in a field follows the apparent course of the sun. But all leaves of plants turn to the sun, place them how you will, light being essential to their thriving.

The lightness of inflammable gas is well known. When bladders of any size are filled with it, they rise upwards, and float in the air. Now, taking advantage of this fact, Mr. Knight suggested that the fine dust by means of which plants are impregnated one from another, is composed of very small globules, filled with this gas—in a word, of small air-balloons. These globules thus float from the male plant through the air, and, striking against the females, are detained by a glue prepared on purpose to stop them, which no sooner moistens the globules than they explode, and their substance remains, the gas flying off which enabled them to float. A provision of a very simple kind is also, in some cases, made to prevent the male and female blossoms of the same plant from breeding together, this being found to hurt the breed of vegetables, just as breeding, in and in, spoils the race of animals. It is contrived that the dust shall be shed by the male blossom before the female of the same plant is ready to be affected by it; so that the impregnation must be performed by the dust of some other plant, and in this way the breed be crossed. The light gas with which the globules are filled is most essential to the operation, as it conveys them to great distances. A plantation of yew-trees has been known, in this way, to impregnate another several hundred yards off.

The contrivance by which some creeper plants are enabled to climb walls and fix themselves, deserves attention. The *Virginia creeper* has a small tendril, ending in a claw, each toe of which has a knob, thickly set with extremely small bristles; they grow into the invisible pores of the wall, and swelling, stick there as long as the plant grows, and prevent the branch from falling; but when the plant dies, they become thin again, and drop out, so that the branch falls down.

The *Vanilla* plant of the West Indies climbs round trees likewise by means of tendrils; but when it has fixed itself, the tendrils drop off, and leaves are formed.

It is found by chemical experiments, that the juice which is in the stomachs of animals (called the *gastric* juice, from a Greek word signifying *the belly*) has very peculiar properties. Though it is for the most part a tasteless, clear, and seemingly a very simple liquor, it nevertheless possesses extraordinary powers of dissolving substances which it touches or mixes with; and it varies in different classes of animals. In one particular it is the same in all animals; it will not attack living matter, but only dead; the consequence of which is, that its powers of eating away and dissolving are perfectly safe to the animals themselves, in whose stomachs it remains without ever hurting them. This juice differs in different animals, according to the food on which they subsist; thus, in birds of prey, as kites, hawks, owls, it only acts upon animal matter, and does not dissolve vegetables. In other birds, and in all animals feeding on plants, as oxen, sheep, hares, it dissolves vegetable matter, as grass, but will not touch flesh of any kind. This has been ascertained by making them swallow balls with meat in them, and several holes drilled through to let the gastric juice reach the meat: no effect was produced upon it. We may further observe, that there is a most curious and beautiful correspondence between this juice in the stomach of different animals and the other parts of their bodies, connected with the important operations of eating and digesting their food. The use of the juice is plainly to convert what they eat into a fluid, from which, by various other processes, all their parts, blood, bones, muscles, &c., are afterwards formed. But the food is first of all to be obtained, and then prepared by bruising, for the action of the juice. Now birds of prey have instruments, their claws and beaks, for tearing and devouring their food (that is, animals of various kinds), but those instruments are useless for picking up and crushing seeds; accordingly, they have a gastric juice which dissolves the animals they eat; while birds, which have only a beak fit for pecking, and eating seeds, have a juice that dissolves seeds, and not flesh. Nay more, it is found that the seeds must be bruised before the juice will dissolve them: this you find by trying the experiment in a vessel with the juice; and accordingly the birds have a gizzard, and animals which graze have flat teeth, which grind and bruise their food, before the gastric juice is to act upon it.

We have seen how wonderfully the *Bee* works, according to rules discovered by man thousands of years after the insect had been following them with perfect accuracy. The same little animal seems to be acquainted with principles of which we are still ignorant. We can, by crossing, vary the forms of cattle with astonishing nicety; but we have no means of altering the nature of an animal once born, by means of treatment and feeding. This power, however, is undeniably possessed by the bees. When the queen bee is lost by death or otherwise, they choose a grub from among those which are born for workers; they make three cells into one, and placing the grub there, they build a tube round it; they afterwards build another cell of a pyramidal form, into which the grub grows; they feed it with peculiar food, and tend it with extreme care. It becomes, when transformed from the worm to the fly, not a worker, but a queen bee.

These singular insects resemble our own species in one of our worst propensities, the disposition to war; but their attention to their sovereign is equally extraordinary, though of a somewhat capricious kind. In a few hours after their queen is lost, the whole hive is in a state of confusion. A singular humming is heard, and the bees are seen moving all over the surface of the combs with great rapidity. The news spreads quickly, and when the queen is restored, quiet immediately succeeds. But if another queen be put upon them, they instantly discover the trick, and, surrounding her, they either suffocate or starve her to death. This happens if the false queen be introduced within a few hours after the first is lost or removed; but if twenty-four hours have elapsed, they will receive any queen, and obey her.

The labours and the policy of the *Ants* are, when closely examined, still more wonderful, perhaps, than those of the *Bees*. Their nest is a city consisting of dwelling-places, halls, streets, and squares into which the streets open. The food they principally like is the honey which comes from another insect found in their neighbourhood, and which they, generally speaking, bring home from day to day as they want it. Late discoveries have shown that they do not eat grain, but live almost entirely on animal food and this honey. Some kinds of ants have the foresight to bring home the insects on whose honey they feed, and keep them in particular cells, where they guard them to prevent their escaping, and feed them with proper vegetable matter, which they do not eat themselves. Nay, they obtain the eggs of those insects, and superintend their hatching, and then rear the young insect until it becomes capable of supplying the desired honey. They sometimes remove them to the strongest parts of their nest, where there are cells apparently fortified for protecting them from invasion. In those cells the insects are kept to supply the wants of the whole ants which compose the population of the city. It is a most singular circumstance in the economy of nature, that the degree of cold at which the ant becomes torpid is also that at which this insect falls into the same state. It is considerably below the freezing-point; so that they require food the greater part of the winter, and if the insects on which they depend for food were not kept alive during the cold in which the ants can move about, the latter would be without the means of subsistence.

How trifling soever this little animal may appear in our climate, there are few more formidable creatures than the ant of some tropical countries. A traveller, who once filled a high station in the French government, Mr. Malouet, has described one of their cities, and, were not the account confirmed by various testimonies, it might seem exaggerated. He observed at a great distance what seemed a lofty structure, and was informed by his guide that it consisted of an ant-hill, which could not be approached without danger of being devoured. Its height was from fifteen to twenty feet, and its base thirty or forty feet square. Its sides inclined, like the lower part of a pyramid, the point being cut off. He was informed that it became necessary to destroy these nests, by raising a sufficient force to dig a trench all round, and fill it with fagots, which were afterwards set on fire; and then battering with cannon from a distance, to drive the insects out and make them run into the flames. This was in South America; and African travellers have met them in the same formidable numbers and strength.

The older writers of books upon the habits of some animals, abound with stories which may be of doubtful credit. But the facts now stated respecting the Ant and Bee, may be relied on as authentic. They are the result of very late observations, and experiments made with great accuracy by several most worthy and intelligent men; and the greater part of them have the confirmation arising from more than one observer having assisted in the inquiries.[*] The habits of *Beavers* are equally well authenticated, and, being more easily observed, are vouched by a greater number of witnesses. These animals, as if to enable them to live and move either on land or water, have two web-feet like those of ducks or water-dogs, and two like those of land animals. When they wish to construct a dwelling-place, or rather city, for it serves the whole body, they choose a level ground with a stream running through it; they then dam up the stream so as to make a pond, and perform the operation as skilfully as we could ourselves. Next they drive into the ground stakes of five or six feet long in rows, wattling each row with twigs, and puddling or filling the interstices with clay, which they ram close in, so as to make the whole solid and water-tight. This dam is likewise shaped on the truest principles; for the upper side next the water slopes, and the side below is perpendicular: the base of the dam is ten or twelve feet thick; the top or narrow part two or three, and it is sometimes as long as one hundred feet.[†] The pond being thus formed and secured, they make their houses round the edge of it; they are cells, with vaulted roofs, and upon piles: they are made of stones, earth, and sticks; the walls are two feet thick, and plastered as neatly as if the trowel had been used. Sometimes they have two or three stories for retreating to in case of floods; and they always have two doors, one towards the water and one towards the land. They keep their winter provisions in stores, and bring them out to use; they make their beds of moss; they live on the bark of trees, gum, and crawfish. Each house holds from twenty to thirty, and there may be from ten to twenty-five houses in all. Some of their communities are larger than others, but there are seldom fewer than two or three hundred inhabitants. In working, they all bear their shares; some gnaw the trees and branches with their teeth, to form stakes and beams; others roll the pieces to the water; others, diving, make holes with their teeth to place the piles in; others collect and carry stones and clay; others beat and mix the mortar; and others carry it on their broad tails, and with these beat it and plaster it. Some superintend the rest, and make signals by sharp strokes with the tail, which are carefully attended to; the beavers hastening to the place where they are wanted to work, or to repair any hole made by the water, or to defend themselves or make their escape, when attacked by an enemy.

The fitness of different animals, by their bodily structure, to the circumstances in which they are found, presents an endless subject of curious inquiry and pleasing contemplation. Thus, the *Camel*, which lives in sandy deserts, has broad spreading hoofs to support him on the loose soil; and an apparatus in his body by which water is kept for many days, to be used when no moisture can be had. As this would be useless in the neighbourhood of streams or wells, and as it would be equally so in the desert, where no water is to be found, there can be no doubt that it is intended to assist in journeying across the sands from one watered spot to another. There is a singular and beautiful provision made in this animal's foot, for enabling it to sustain the fatigue of journeys under the pressure of its great weight. Besides the yielding of the bones and ligaments, or bindings, which gives elasticity to the foot of the deer and other animals, there is in the Camel's foot, between the horny sole and the bones, a cushion, like a ball, of soft matter, almost fluid, but in which there is a mass of threads extremely elastic, interwoven with the pulpy substance. The cushion thus easily changes its shape when pressed; yet it has such an elastic spring, that the bones of the foot press on it uninjured by the heavy body which they support, and this huge animal steps as softly as a cat.

Nor need we flee to the desert in order to witness an example of skilful structure; the limbs of the *Horse* display it strikingly. The bones of the foot are not placed directly under the weight; if they were in an upright position, they would make a firm pillar, and every motion would cause a shock. They are placed slanting or oblique, and tied together by an elastic binding on their lower surfaces, so as to form springs as exact as those which we make of leather and steel for carriages. Then the flatness of the hoof, which stretches out on each side, and the frog coming down in the middle between the quarters, adds greatly to the elasticity of the machine. Ignorant of this, ill-informed farriers nail the shoe in such a manner as to fix the quarters, and cause permanent contraction of the bones, ligaments, and hoof—so that the elasticity is destroyed; every step is a shock; inflammation and lameness ensue.*

---

[*] A singular circumstance occasioned this in the case of Mr. Huber, by far the most eminent of these naturalists: he was quite blind, and performed all his experiments by means of assistants.

[†] If the base be twelve, and the top three feet thick, and the height six feet, the face must be the side of a right-angled triangle whose height is eight feet. This would be the exact proportion which there ought to be, upon mathematical principles, to give the greatest resistance possible to the water in its tendency to turn the dam round, provided the materials of which it is made were lighter than water in the proportion of 44 to 100. But the materials are probably more than twice as heavy as water, and the form of so flat a dike is taken, in all likelihood, in order to guard against a more imminent danger—that of the dam being carried away by being shoved forwards. We cannot calculate what the proportions are which give the greatest possible resistance to this tendency, without knowing the tenacity of the materials, as well as their specific gravity. It may very probably be found that the construction is such as to secure the most completely, against the two pressures at the same time.

The *Rein-deer* inhabits a country covered with snow the greater part of the year. Observe how admirably its hoof is formed for going over that cold and light substance, without sinking in it or being frozen. The under side is covered entirely with hair, of a warm and close texture; and the hoof, altogether, is very broad, acting exactly like the snow-shoes which men have constructed for giving them a larger space to stand on than their feet, and thus avoid sinking. Moreover, the deer spreads the hoof as wide as possible when it touches the ground: but, as this breadth would be inconvenient in the air, by occasioning a greater resistance while he is moving along, no sooner does he lift the hoof than the two parts into which it is cloven fall together, and so lessen the surface exposed to the air, just as we may recollect the birds doing with their bodies and wings. The shape and structure of the hoof are also well adapted to scrape away the snow, and enable the animal to get at the particular kind of moss (or *lichen*) on which he feeds. This plant, unlike others, is in its full growth during the winter season; and the Rein-deer accordingly thrives, from its abundance, at the season of his greatest use to man, notwithstanding the unfavourable effects of extreme cold upon the animal system.

There are some insects, of which the males have wings, and the females are grubs or worms. Of these, the *Glow-worm* is the most remarkable: it is the female, and the male is a fly, which would be unable to find her out, creeping as she does in the dark lanes, but for the shining light which she gives to attract him.

There is a singular fish found in the Mediterranean, called the *Nautilus*, from its skill in navigation. The back of its shell resembles the hulk of a ship; on this it throws itself, and spreads two thin membranes to serve for two sails, paddling itself on with its feet or feelers, as oars.

The *Ostrich* lays and hatches her eggs in the sands: her form being ill-adapted for sitting on them, she has a natural oven furnished by the sand, and the strong heat of the sun. The *Cuckoo* is known to build no nest for herself, but to lay in the nests of other birds; but late observations show that she does not lay indiscriminately in the nests of all birds; she only chooses the nests of those which have bills of the same kind with herself, and therefore feed on the same kind of food. The *Duck*, and other birds breeding in muddy places, have a peculiar formation of the bill: it is both made so as to act like a strainer, separating the finer from the grosser parts of the liquid, and it is more furnished with nerves near the point than the bills of birds which feed on substances more exposed to the light; so that being more sensitive, it serves better to grope in the dark stream for food. The bill of the *Snipe* is covered with a curious network of nerves for the same purpose; but the most singular provision of this kind is observed in a bird called the *Toucan*, or *Egg-sucker*, which chiefly feeds on the eggs found in birds' nests, and in countries where these are very deep and dark. Its bill is broad and long; when examined, it appears completely covered with branches of nerves in all directions; so that, by groping in a deep and dark nest it can feel its way as accurately as the finest and most delicate finger could. Almost all kinds of birds build their nests of materials found where they inhabit, or use the nests of other birds; but the *Swallow of Java* lives in rocky caverns on the sea, where there are no materials at all for the purpose of building. It is therefore so formed as to secrete in its body a kind of slime, with which it makes a nest, much prized as a delicate food in Eastern countries.

Plants, in many remarkable instances, are provided for by equally wonderful and skilful contrivances. There is one, the *Muscipula*, *Fly-trap*, or *Fly-catcher*, which has small prickles in the inside of two leaves, or half-leaves, joined by a hinge; a juice or syrup is provided on their inner surface, which acts as a bait to allure flies. There are several small spines or prickles standing upright in this syrup, and upon the only part of each leaf that is sensitive to the touch. When the fly, therefore, settles upon this part, its touching, as it were, the spring of the trap, occasions the leaves to shut, and kill and squeeze the insect; whose juices, and the air arising from their rotting, serve as food to the plant.

In the West Indies, and in other hot countries of South America, where rain sometimes does not fall for a great length of time, a kind of plant called the *Wild-pine* grows upon the branches of the trees, and also on the bark of the trunk. It has hollow or bag-like leaves, so formed as to make little reservoirs of water, the rain falling into them through channels which close at the top when full, and prevent it from evaporating. The seed of this useful plant has small floating threads, by which, when carried through the air, it catches any tree in the way, and falls on it and grows. Wherever it takes root, though on the under side of a bough, it grows straight upwards, otherwise the leaves would not hold water. It holds in one leaf from a pint to a quart; and although it must be of great use to the trees it grows on, to birds and other animals its use is even greater.

"When we find these pines," says Dampier, the famous navigator, "we stick our knives into the leaves just above the root, and the water gushing out, we catch it in our hats, as I myself have frequently done, to my great relief."

---

* Mr. Bracey Clarke has contrived an expanding shoe, which, by a joint in front, opens and contracts so as to obviate the evils of the common process.

Another tree, called the *Water-with*, in Jamaica, has similar uses: it is like a vine in size and shape, and though growing in parched districts, is yet so full of clear sap or water, that by cutting a piece two or three yards long, and merely holding it to the mouth, a plentiful draught is obtained. In the East, there is a plant somewhat of the same kind, called the *Bejuco*, which grows near other trees and twines round them, with its end hanging downwards, but so full of juice, that, on cutting it, a good stream of water spouts from it; and this, not only by the stalk touching the tree so closely must refresh it, but affords a supply to animals, and to the weary herdsman on the mountains. Another plant, the *Nepenthes distillatoria*, is found in the same regions, with a yet more singular structure. It has natural mugs or tankards hanging from its leaves, and holding each from a pint to a quart of very pure water. Two singular provisions are to be marked in this vegetable. There grows over the mouth of the tankard, a leaf nearly its size and shape, like a lid or cover, which prevents evaporation from the sun's rays; and the water that fills the tankard is perfectly sweet and clear, although the ground in which the plant grows is a marsh of the most muddy and unwholesome kind. The process of vegetation filtrates or distils the liquid, so as to produce from the worst, the purest water.* The *Palo de Vaca*, or cow-tree, grows in South America, upon the most dry and rocky soil, and in a climate where for months not a drop of rain falls. On piercing the trunk, however, a sweet and nourishing milk is obtained, which the natives gladly receive in large bowls. If some plants thus furnish drink, where it might least be expected, others prepare, as it were, in the desert, the food of man in abundance. A single *Tapioca* tree is said to afford, from its pith, the whole sustenance of several men for a season.

V. ADVANTAGES AND PLEASURES OF SCIENCE.

AFTER the many instances or samples which have now been given of the nature and objects of Natural Science, we might proceed to a different field, and describe in the same way the other grand branch of human knowledge, that which teaches the properties or habits of *Mind*—the *intellectual faculties* of man, or the powers of his understanding, by which he perceives, imagines, remembers, and reasons;—his *moral faculties*, or the feelings and passions which influence him;—and lastly, as a conclusion or result drawn from the whole, his *duties* both towards himself as an individual, and towards others as a member of society: which last head opens to our view the whole doctrines of *political science*, including the nature of *governments*, of *policy*, and generally of *laws*. But we shall abstain entirely from entering at all upon this field, and shall now take up the subject more particularly pointed at through the course of the foregoing observations, and to illustrate which they have been framed—namely, the Use and Pleasure of Scientific Studies.

Man is composed of two parts, body and mind, connected indeed together, but wholly different from one another. The nature of the union—the part of our outward and visible frame in which it is peculiarly formed—or whether the soul be indeed connected or not with any particular portion of the body, so as to reside there—are points as yet wholly hid from our knowledge, and which are likely to remain for ever concealed. But this we know, as certainly as we can know any truth, that there is such a thing as the *Mind;* and that we have at the least as good proof of its existence, independent of the Body, as we have of the existence of the Body itself. Each has its uses, and each has its peculiar gratifications. The bounty of Providence has given us outward senses to be employed, and has furnished the means of gratifying them in various kind, and in ample measure. As long as we only taste those pleasures according to the rules of prudence and of our duty, that is, in moderation for our own sakes, and in harmlessness towards our neighbours, we fulfil rather than thwart the purpose of our being. But the same bountiful Providence has endowed us with the higher nature also—with understandings as well as with senses—with faculties that are of a more exalted order, and admit of more refined enjoyments, than any to which the bodily frame can minister; and by pursuing such gratifications, rather than those of mere sense, we fulfil the most exalted ends of our creation, and obtain both a present and a future reward. These things are often said, but they are not therefore the less true, or the less worthy of deep attention. Let us mark their practical application to the occupations and enjoyments of all branches of society, beginning with those who form the great bulk of every community, the working classes, by what names soever their vocations may be called—professions, arts, trades, handicrafts, or common labour.

1. The first object of every man, who has to depend upon his own exertions, must needs be to provide for his daily wants. This is a high and important office; it deserves his utmost attention; it includes some of his most sacred duties, both to himself, his kindred, and his country; and although, in performing this task, he is only influenced by a regard to his own interest, or by his necessities, yet it is an employment which renders him truly the best benefactor of the community he belongs to. All other pursuits must give way to this; the hours which he devotes to learning must be after he has done his work; his independence, without which he is not fit to be called a man, requires first of all that he should have insured for himself, and those dependent on him, a comfortable subsistence, before he can have a right to

---

* A specimen of this curious plant, though of a small size, is to be found in the fine collection at Wentworth, reared by Mr. Cooper.

taste any indulgence, either of his senses or of his mind; and the more he learns—the greater progress he makes in the sciences—the more will he value that independence, and the more will he prize the industry, the habits of regular labour, whereby he is enabled to secure so prime a blessing.

In one view, it is true, the progress which he makes in science may help his ordinary exertions, the main business of every man's life. There is hardly any trade or occupation in which useful lessons may not be learnt by studying one science or another. The necessity of science to the more liberal professions is self-evident; little less manifest is the use to their members of extending their knowledge beyond the branches of study with which their several pursuits are peculiarly conversant. But the other departments of industry derive hardly less benefit from the same source. To how many kinds of workmen must a knowledge of Mechanical Philosophy be useful! To how many others does Chemistry prove almost necessary! Every one must with a glance perceive that to engineers, watch-makers, instrument-makers, bleachers, and dyers, those sciences are most useful, if not necessary. But carpenters and masons are surely likely to do their work better for knowing how to measure, which Practical Mathematics teaches them, and how to estimate the strength of timber, of walls, and of arches, which they learn from Practical Mechanics; and they who work in various metals are certain to be the more skilful in their trades for knowing the nature of those substances, and their relations to both heat and other metals, and to the gases and liquids they come in contact with. Nay, the farm servant, or day-labourer, whether in his master's employ, or tending the concerns of his own cottage, must derive great practical benefit,—must be both a better servant, and a more thrifty and therefore comfortable, cottager, for knowing something of the nature of soils and manures, which Chemistry teaches, and something of the habits of animals, and the qualities and growth of plants, which he learns from Natural History and Chemistry together. In truth, though a man be neither mechanic nor peasant, but only one having a pot to boil, he is sure to learn from science lessons which will enable him to cook his morsel better, save his fuel, and both vary his dish and improve it. The art of good and cheap cookery is intimately connected with the principles of chemical philosophy, and has received much, and will yet receive more, improvement from their application. Nor is it enough to say, that philosophers may discover all that is wanted, and may invent practical methods, which it is sufficient for the working man to learn by rote without knowing the principles. He never will work so well if he be ignorant of the principles; and for a plain reason:—if he only learn his lesson by rote, the least change of circumstances puts him out. Be the method ever so general, cases will always arise in which it must be varied in order to apply; and if the workman only know the rule without knowing the reason, he must be at fault the moment he is required to make any new application of it. This, then, is the *first* use of learning the principles of science: it makes men more skilful, expert, and useful in the particular kinds of work by which they are to earn their bread, and by which they are to make it go far and taste well when earned.

2. But another use of such knowledge to handicraftsmen is equally obvious: it gives every man a chance, according to his natural talents, of becoming an improver of the art he works at, and even a discoverer in the sciences connected with it. He is daily handling the tools and materials with which new experiments are to be made; and daily witnessing the operations of nature, whether in the motions and pressures of bodies, or in their chemical actions on each other. All opportunities of making experiments must be unimproved, all appearances must pass unobserved, if he have no knowledge of the principles; but with this knowledge he is more likely than another person to strike out something new which may be useful in art, or curious or interesting in science. Very few great discoveries have been made by chance and by ignorant persons; much fewer than is generally supposed. It is commonly told of the steam-engine, that an idle boy being employed to stop and open a valve, saw that he could save himself the trouble of attending and watching it, by fixing a plug upon a part of the machine which came to the place at the proper times, in consequence of the general movement. This is possible, no doubt; though nothing very certain is known respecting the origin of the story; but improvements of any value are very seldom indeed so easily found out, and hardly another instance can be named of important discoveries so purely accidental. They are generally made by persons of competent knowledge, and who are in search of them. The improvements of the Steam-engine by Watt resulted from the most learned investigation of mathematical, mechanical, and chemical truths. Arkwright devoted many years, five at the least, to his invention of spinning-jennies, and he was a man perfectly conversant in everything that relates to the construction of machinery: he had minutely examined it, and knew the effects of each part, though he had not received anything like a scientific education. If he had, we should in all probability have been indebted to him for scientific discoveries as well as practical improvements. The most beautiful and useful invention of late times, the Safety-lamp, was the reward of a series of philosophical experiments made by one thoroughly skilled in every branch of chemical science. Again, the process of Refining Sugar, by which more money has been made in a shorter time, and with less risk and trouble, than was ever perhaps gained from an invention, was discovered by a most accomplished chemist,* and was the fruit of a long course of experiments, in the progress of which, known philosophical principles were constantly applied, and one or two new principles ascertained. But in so far as chance has anything to do with discovery, surely it is worth the while of those who are constantly

---

* Edward Howard, brother of the late Duke of Norfolk.

working in particular employments to obtain the knowledge required, because their chances are greater than other people's of so applying that knowledge as to hit upon new and useful ideas: they are always in the way of perceiving what is wanting, or what is amiss in the old methods; and they have a better chance of making the improvements. In a word, to use a common expression, they are in the way of good luck; and if they possess the requisite information, they can take advantage of it when it comes to them. This, then, is the *second* great use of learning the sciences: it enables men to make improvements in the arts, and discoveries in philosophy, which may directly benefit themselves and mankind.

3. Now, these are the *practical* advantages of learning; but the *third* benefit is, when rightly considered, just as practical as the other two—the pleasure derived from mere knowledge, without any view to our own bodily enjoyments: and this applies to all classes, the idle as well as the industrious, if, indeed, it be not peculiarly applicable to those who enjoy the inestimable blessing of having time at their command. Every man is by nature endowed with the power of gaining knowledge; and the taste for it, the capacity to be pleased with it, forms equally a part of the natural constitution of his mind. It is his own fault, or the fault of his education, if he derive no gratification from it. There is a satisfaction in knowing what others know—in not being more ignorant than those we live with: there is a satisfaction in knowing what others do not know—in being more informed than they are. But this is quite independent of the pure pleasure of knowledge—of gratifying a curiosity implanted in us by Providence, to lead us towards the better understanding of the universe in which our lot is cast, and the nature wherewithal we are clothed. That every man is capable of being delighted with extending his information upon matters of science will be evident from a few plain considerations.

Reflect how many parts of the reading, even of persons ignorant of all sciences, refer to matters wholly unconnected with any interest or advantage to be derived from the knowledge acquired. Every one is amused with reading a story: a romance may divert some, and a fairy tale may entertain others; but no benefit beyond the amusement is derived from this source: the imagination is gratified; and we willingly spend a good deal of time and a little money in this gratification, rather than in resting after fatigue, or in any other bodily indulgence. So we read a newspaper, without any view to the advantage we are to gain from learning the news, but because it interests and amuses us to know what is passing. One object, no doubt, is to become acquainted with matters relating to the welfare of the country; but we also read the occurrences which do little or not at all regard the public interests, and we take a pleasure in reading them. Accidents, adventures, anecdotes, crimes, and a variety of other things amuse us, independent of the information respecting public affairs, in which we feel interested as citizens of the state, or as members of a particular body. It is of little importance to inquire how and why these things excite our attention, and wherefore the reading about them is a pleasure; the fact is certain; and it proves clearly that there is a positive enjoyment in knowing what we did not know before; and this pleasure is greatly increased when the information is such as excites our surprise, wonder, or admiration. Most persons who take delight in reading tales of ghosts, which they know to be false, and feel all the while to be silly in the extreme, are merely gratified, or rather occupied with the strong emotions of horror excited by the momentary belief, for it can only last an instant. Such reading is a degrading waste of precious time, and has even a bad effect upon the feelings and the judgment.* But true stories of horrid crimes, as murders, and pitiable misfortunes, as shipwrecks, are not much more instructive. It may be better to read these than to sit yawning and idle—much better than to sit drinking or gaming, which, when carried to the least excess, are crimes in themselves, and the fruitful parents of many more. But this is nearly as much as can be said for such vain and unprofitable reading. If it be a pleasure to gratify curiosity, to know what we were ignorant of, to have our feelings of wonder called forth, how pure a delight of this very kind does Natural Science hold out to its students! Recollect some of the extraordinary discoveries of Mechanical Philosophy. How wonderful are the laws that regulate the motions of fluids! Is there anything in all the idle books of tales and horrors more truly astonishing than the fact, that a few pounds of water may, by mere pressure, without any machinery—by merely being placed in a particular way, produce an irresistible force? What can be more strange, than that an ounce weight should balance hundreds of pounds, by the intervention of a few bars of thin iron? Observe the extraordinary truths which Optical Science discloses. Can anything surprise us more, than to find that the colour of white is a mixture of all others—that red, and blue, and green, and all the rest, merely by being blended in certain proportions, form what we had fancied rather to be no colour at all, than all colours together? Chemistry is not behind in its wonders. That the diamond should be made of the same material with coal; that water should be chiefly composed of an inflammable substance; that acids should be, for the most part, formed of different kinds of air, and that one of those acids, whose strength can dissolve almost any of the metals, should consist of the selfsame ingredients with the common air we breathe; that salts should be of a metallic nature, and composed, in great part, of metals, such as potassium, &c.,

---

* *Children's books* have at all times been made upon the pernicious plan of exciting wonder, generally horror, at whatever risk. The folly and misery occasioned by this error, it would be difficult to estimate. The time may come when it will be felt and understood. At present, the inveterate habits of parents and nurses prevent the children from benefiting by the excellent lessons of many of our popular writers.

yet lighter than water, and which, without any heating, take fire upon being exposed to the air, and, by burning, form the substance so abounding in saltpetre and in the ashes of burnt wood: these, surely, are things to excite the wonder of any reflecting mind—nay, of any one but little accustomed to reflect. And yet these are trifling when compared to the prodigies which Astronomy opens to our view: the enormous masses of the heavenly bodies; their immense distances; their countless numbers, and their motions, whose swiftness mocks the uttermost efforts of the imagination.

Akin to the pleasure of contemplating new and extraordinary truths, is the gratification of a more learned curiosity, by tracing resemblances and relations between things, which, to common apprehension, seem widely different. Mathematical science, to thinking minds, affords this pleasure in a high degree. It is agreeable to know that the three angles of every triangle, whatever be its size, howsoever its sides may be inclined to each other, are always, of necessity, when taken together, the same in amount: that any regular kind of figure whatever, upon the one side of a right-angled triangle, is equal to the two figures of the same kind upon the two other sides, whatever be the size of the triangle: that the properties of an oval curve are extremely similar to those of a curve which appears the least like it of any, consisting of two branches of infinite extent, with their backs turned to each other. To trace such unexpected resemblances is, indeed, the object of all philosophy; and experimental science, in particular, is occupied with such investigations, giving us general views, and enabling us to explain the appearances of nature; that is, to show how one appearance is connected with another. But we are now considering only the gratification derived from learning these things. It is surely a satisfaction, for instance, to know that the same thing, or motion, or whatever it is, which causes the sensation of heat, causes also fluidity, and expands bodies in all directions; that electricity, the light which is seen on the back of a cat when slightly rubbed on a frosty evening, is the very same matter with the lightning of the clouds;—that plants breathe like ourselves, but differently by day and by night;—that the air which burns in our lamps enables a balloon to mount, and causes the globules of the dust of plants to rise, float through the air, and continue their race—in a word, is the immediate cause of vegetation. Nothing can at first view appear less like, or less likely to be caused by the same thing, than the processes of burning and of breathing—the rust of metals and burning—an acid and rust—the influence of a plant on the air it grows in by night, and of an animal on the same air at any time, nay, and of a body burning in that air; and yet all these are the same operation. It is an undeniable fact, that the very same thing which makes the fire burn, makes metals rust, forms acids, and enables plants and animals to breathe; that these operations, so unlike to common eyes, when examined by the light of science, are the same—the rusting of metals—the formation of acids—the burning of inflammable bodies—the breathing of animals—and the growth of plants by night. To know this is a positive gratification. Is it not pleasing to find the same substance in various situations extremely unlike each other;—to meet with fixed air as the produce of burning, of breathing, and of vegetation:—to find that it is the choke-damp of mines, the bad air in the grotto at Naples, the cause of death in neglecting brewers' vats, and of the brisk and acid flavour of Seltzer and other mineral springs? Nothing can be less like than the working of a vast steam-engine of the old construction, and the crawling of a fly upon the window. Yet we find that these two operations are performed by the same means, the weight of the atmosphere, and that a sea-horse climbs the ice-hills by no other power. Can anything be more strange to contemplate? Is there, in all the fairy-tales that ever were fancied, anything more calculated to arrest the attention and to occupy and to gratify the mind, than this most unexpected resemblance between things so unlike to the eyes of ordinary beholders? What more pleasing occupation than to see uncovered and bared before our eyes the very instrument and the process by which Nature works? Then we raise our views to the structure of the heavens; and are again gratified by tracing accurate, but most unexpected resemblances. Is it not in the highest degree interesting to find, that the power which keeps this earth in its shape, and in its path, wheeling upon its axis and round the sun, extends over all the other worlds that compose the universe, and gives to each its proper place and motion; that this same power keeps the moon in her path round our earth, and our earth in its path round the sun, and each planet in its path; that the same power causes the tides upon our globe, and the peculiar form of the globe itself; and that, after all, it is the same power which makes a stone fall to the ground? To learn these things, and to reflect upon them, occupies the faculties, fills the mind, and produces certain as well as pure gratification.

But if the knowledge of the doctrines unfolded by science be pleasing, so is the being able to trace the steps by which those doctrines are investigated, and their truth demonstrated: indeed, you cannot be said, in any sense of the word, to have learnt them, or to know them, if you have not so studied them as to perceive how they are proved. Without this you never can expect to remember them long, or to understand them accurately; and that would of itself be reason enough for examining closely the grounds they rest on. But there is the highest gratification of all, in being able to see distinctly those grounds, so as to be satisfied that a belief in the doctrines is well founded. Hence to follow a demonstration of a grand mathematical truth—to perceive how clearly and how inevitably one step succeeds another, and how the whole steps lead to the conclusion—to observe how certainly and unerringly the reasoning goes on from things perfectly self-evident, and by the smallest addition at each step, every one being as easily taken after the one before, as the first step of all was, and yet the result being something not only far from self-evident, but so general and strange, that you can hardly believe it to be true, and are only convinced of it by going over the whole reasoning—this operation of the understanding, to those who so exercise themselves, always affords the highest delight. The contemplation of experimental inquiries, and the examination of reasoning founded upon the facts which our experiments and observations disclose, is another fruitful source of enjoyment, and no other means can be devised for either imprinting the results upon our memory, or enabling us really to enjoy the whole pleasures of science. They who found the study of some branches dry and tedious at the first, have generally become more and more interested as they went on; each difficulty overcome, gives an additional relish to the pursuit, and makes us feel, as it were, that we have by our work and labour established a right of property in the subject. Let any man pass an evening in vacant idleness, or even in reading some silly tale, and compare the state of his mind when he goes to sleep or gets up next morning with its state some other day, when he has passed a few hours in going through the proofs, by facts and reasoning, of some of the great doctrines in Natural Science, learning truths wholly new to him, and satisfying himself by careful examination of the grounds on which known truths rest, so as to be not only acquainted with the doctrines themselves, but able to show why he believes them, and to prove before others that they are true;—he will find as great a difference as can exist in the same being—the difference between looking back upon time unprofitably wasted, and time spent in self-improvement: he will feel himself in the one case listless and dissatisfied, in the other comfortable and happy: in the one case, if he do not appear to himself humbled, at least he will not have earned any claim to his own respect; in the other case, he will enjoy a proud consciousness of having, by his own exertions, become a wiser and therefore a more exalted creature.

To pass our time in the study of the sciences, in learning what others have discovered, and in extending the bounds of human knowledge, has, in all ages, been reckoned the most dignified and happy of human occupations; and the name of Philosopher, or Lover of Wisdom, is given to those who lead such a life. But it is by no means necessary that a man should do nothing else than study known truths, and explore new, in order to earn this high title. Some of the greatest philosophers, in all ages, have been engaged in the pursuits of active life; and an assiduous devotion of the bulk of our time to the work which our condition requires, is an important duty, and indicates the possession of practical wisdom. This, however, does by no means hinder us from applying the rest of our time, beside what nature requires for meals and rest, to the study of science; and he who, in whatever station his lot may be cast, works his day's work, and improves his mind in the evening, as well as he who, placed above such necessity, prefers the refined and elevating pleasures of knowledge to the low gratification of the senses, richly deserves the name of a **True Philosopher.**

One of the most delightful treats which science affords us is the knowledge of the extraordinary powers with which the human mind is endowed. No man, until he has studied philosophy, can have a just idea of the great things for which Providence has fitted his understanding—the extraordinary disproportion which there is between his natural strength and the powers of his mind and the force he derives from them. When we survey the marvellous truths of Astronomy, we are first of all lost in the feeling of immense space, and of the comparative insignificance of this globe and its inhabitants. But there soon arises a sense of gratification and new wonder at perceiving how so insignificant a creature has been able to reach such a knowledge of the unbounded system of the universe—to penetrate, as it were, through all space, and become familiar with the laws of nature at distances so enormous as to baffle our imagination—to be able to say, not merely that the Sun has 329,630 times the quantity of matter which our globe has, Jupiter 308$\frac{2}{10}$, and Saturn 93$\frac{1}{2}$ times; but that a pound of lead weighs at the Sun 22 lbs. 15 ozs. 16 dwts. 8 grs. and $\frac{2}{3}$ of a grain! at Jupiter 2 lbs. 1 oz. 19 dwts. 1 gr. $\frac{20}{43}$; and at Saturn 1 lb. 3 ozs. 8 dwts. 20 grs. $\frac{1}{11}$th part of a grain! And what is far more wonderful, to discover the laws by which the whole of this vast system is held together and maintained through countless ages in perfect security and order. It is surely no mean reward of our labour to become acquainted with the prodigious genius of those who have almost exalted the nature of man above its destined sphere, when, admitted to a fellowship with these loftier minds, we discover how it comes to pass that, by universal consent, they hold a station apart, rising over all the Great Teachers of mankind, and spoken of reverently, as if NEWTON and LAPLACE were not the names of mortal men.

The highest of all our gratifications in the contemplations of science remains: we are raised by them to an understanding of the infinite wisdom and goodness which the Creator has displayed in his works. Not a step can we take in any direction without perceiving the most extraordinary traces of design; and the skill everywhere conspicuous is calculated, in so vast a proportion of instances, to promote the happiness of living creatures, and especially of our own kind, that we can feel no hesitation in concluding that, if we knew the whole scheme of Providence, every part would be found in harmony with a plan of absolute benevolence. Independently, however, of this most consoling inference, the delight is inexpressible of being able to follow, as it were, with our eyes, the marvellous works of the Great Architect of Nature—to trace the unbounded power and exquisite skill which are exhibited in the most minute, as well as the mightiest parts of his system. The pleasure derived from this study is unceasing, and so various, that it never tires the appetite. But it is unlike the low gratifications of sense in another respect: while those hurt the health, debase the understanding, and corrupt the feelings, this elevates and refines our nature, teaching us to look upon all earthly objects as insignificant, and below our notice, except the pursuit of knowledge and the cultivation of virtue; and giving a dignity and importance to the enjoyment of life, which the frivolous and the grovelling cannot even comprehend.

Let us, then, conclude, that the Pleasures of Science go hand in hand with the solid benefits derived from it; that they tend, unlike other gratifications, not only to make our lives more agreeable, but better; and that a rational being is bound by every motive of interest and of duty, to direct his mind towards pursuits which are found to be the sure path of Virtue as well as of Happiness.

THE

CIRCLE OF THE SCIENCES;

A CYCLOPÆDIA

OF

EXPERIMENTAL, CHEMICAL, MATHEMATICAL, AND MECHANICAL PHILOSOPHY,

AND NATURAL HISTORY.

INTRODUCTION TO PHYSICS.

At a time when the applications of Science are so numerous and highly appreciated, it would be a work of supererogation to attempt to urge their value on the intelligent reader. It may, however, not be out of place, to enquire by what means Experimental Philosophy has attained to its present high rank, either as an object of study, or in its applications to the various requirements of civilised life.

From the earliest ages, the phenomena of Nature must have been deeply investigated by intelligent observers. The labours of Archimedes, Ptolemy, Thales, and others, evidence that there have been those in olden times who delighted to enquire into the reasons and causes of the varied effects they witnessed. Indeed, Electricity—a branch of Science which, during the last half-century, has been applied to so many purposes—was known in some of its effects at least two thousand years ago. Of Geometry and Astronomy, the oldest records extant prove that there were many ardent followers.

But, although a branch of Science has its origin in observation, still its progress is only effected by the mental process of sound induction; and in this department of Philosophy, the ancients were eminently deficient. Having observed an effect, they, in most cases, hastily proceeded to seek a reason; and having to contend with those prejudices of which Lord Bacon speaks so eloquently, they assigned causes which met special cases only. Hence they were at last compelled to invent imaginary ones, which, as they only explained a few collateral effects, could not be generalised. The result of this was, that no branch of Science, properly so called, was ever established: guess-work and empiricism occupied the place of sound reasoning, and mists and mysticism were the final results of their researches in most instances.

The Alchemists of the middle ages fall under the same category as the ancients. They had but one object in view—the conversion of the base into the precious metals; hence every occurrence that presented itself to their notice, which they conceived to be not relevant to their pursuit, was entirely neglected, or ridiculously philosophised on. They preferred, indeed, to teach Nature, rather than to be taught by her; and thus it can be matter of no surprise that, under their auspices, Science made no progress.

Eventually, however, a brighter intellectual day dawned. Experiment became the foundation; fact the superstructure; whilst theory was but the scaffolding to the temple: and as soon as the system was adopted of tracing causes from their effects, and of arranging such, that one theory might connect many causes, Experimental Science advanced with rapid strides. From its lofty abode in the time of Copernicus and Galileo, it has since descended, and has become, as it were, the household god of even the very peasant of the land, and the proximate cause of most of the comforts and conveniences of our existence.

It is not, however, on account of the material advantages which Philosophy affords, that its pursuit is most to be admired. Next to the great object of man's existence in this world—the cultivation of religious sentiments—the expansion of the human mind immediately succeeds in value. And it is impossible to point out any other study which more fully calls out and exercises the mental powers, than that of Nature. The perceptive faculties are employed in investigation and observation; the reasoning power in arranging causes; and the reflective in focalising the rays of light continually emitted: in fact, all the powers of the mind are thus braced and made ready for answering every call which can be made on them.

In arranging the subjects included in the following pages, it has been attempted to make the simple to introduce and prepare the way for the complex. By thus progressing from known to obscure matters, it is hoped that the way of Science has been made plain, although no royal road has been opened out. The persistent attention of the reader has been assumed to have been granted by him; and it is earnestly hoped that the demonstrations herein set forth, may result in the comparatively easy solution of some of the most difficult, as well as the plainer problems in Experimental and Natural Science.

In pursuance of this plan, it will be necessary that we should enquire into those properties possessed by every kind of matter; and despite of all the sophisms of a class of metaphysicians, it will be impossible to define matter otherwise than as that which can be weighed, measured, and perceived by the senses. The speculations of Berkeley and others, however ingenious they may be, have a great tendency, if followed to their logical consequences, to restore the days of philosophical darkness, in which imagination was the *ignis fatuus* which led men astray from the true path of induction.

The leading properties of matter are *Extension*, *Impenetrability*, and *Inertia*, and they are characteristic; for if but one atom existed in the universe, it must necessarily have those. If more than one particle exist, two forces would be called into operation. By that of gravitation, each particle would be attracted mutually; by cohesion, the two would unite, and so form a mass. Thus, by the attraction of gravitation, masses affect each other's position; whilst by the attraction of cohesion, the masses are themselves formed and held together.

It will be most convenient to deal with these properties and forces individually; and to this end it will be first necessary to define the term "atom."

ATOMS.—The original signification of the term is simply, "that which cannot be divided." To such an idea it has been objected, that it is impossible to conceive any particle so small that it cannot be bi-sected or otherwise cut into parts. Mathematical reasoning and demonstration have been adduced in support of this view; and perhaps the most ingenious attempt is that wherein the mutual relationship of parallel lines and angles are employed. As, however, geometricians are compelled to assume that a point occupies no space—that a line has length, but no breadth—so it may be permitted to the physicist to assume, that an atom is such a particle of matter as to be indivisible by physical means; and in this sense the term "atom" will be in future employed by us.

Assuming, for the present, that a body is composed of a number of atoms held together by their attraction for each other, it may be interesting to consider some facts in reference to the divisibility to which a body may be subjected without losing its general and individual properties. The examples of such instances are so numerous as to make a selection most difficult. The following, however, may be adduced, on account of their recent discovery:—

Example 1.—In a cubic inch of chalk, as obtained from the rock, there are the remains of many millions of animalcules, each of which had possessed, during life, all the organs necessary to its independent existence.

Example 2.—It has been found that silver exists in a soluble state in sea-water; but in such minute quantities as to have escaped the notice of the most careful analysts, till lately, when a small portion of the solid metal was discovered as a film on the coppered bottom of a vessel, and had been collected from the immense quantity of water through which the ship had sailed during a long voyage.

The extension of metals by hammering, and in the processes of wire-drawing, are familiar illustrations of a similar nature.

EXTENSION.—This term, in its philosophical sense, defines that property of matter by which it occupies space; and, as it appears at once so evidently a quality of bodies, we pass on to another property, Impenetrability, which is not so self-evident, when considered in certain aspects.

IMPENETRABILITY.—By this is meant that no two bodies can occupy the same space at the same time. There are many *apparent* exceptions to this, which, however, neither have, nor can have, any foundation in fact. Thus, on adding strong sulphuric acid to cold water, in a long glass vessel, the two liquids, on being mixed, will occupy less space than they did separately. This fact is, however, easily explained. No state of matter is really solid; for each mass has its atoms at a distance from each other; the divisions between them being called pores or interstices. In the instance just adduced, the particles are brought closer to each other, so that whilst the *mass* may occupy *less* space, the individual atoms are impenetrable, or, in other words, could not at the same time occupy each other's place. India-rubber, cork, atmospheric air, &c., all seem to create paradoxes in reference to this doctrine; which, however, are easily explained away, and on which further remarks will be made under the head of Cohesive Attraction. Familiar instances illustrate the impenetrability of solids; such as the insertion of a nail, chisel, or saw into wood, &c., where the particles of the wood are merely thrust aside, to make way for the body introduced between them.

INERTIA.—That no inanimate mass can be set in motion spontaneously, will be readily admitted; its converse, that no body can come to rest spontaneously, may, however, be difficult to understand, owing to daily occurrences seeming to demonstrate the opposite conclusion. A little consideration, however, will easily remove any doubts on these two doctrines of the Inertia, or the immovability of matter. All matter requires the application of external force to remove it from its position; and so far as terrestrial objects are concerned, any force so applied is instantly opposed in most cases by two others—namely, those of gravitation and resistance. Taking, for instance, an extreme case of motion—such as the flight of a bullet from the muzzle of a rifle—it is found that the ball instantly falls towards the earth by virtue of gravitative force, and it is also diverted right or left, or opposed in its forward progress, by the resistance of the air to its passage. The former of these forces may be temporarily suspended, as in the case of a balloon; the latter as in the vacuum of an air-pump, wherein a penny and a feather will, owing to the absence of air, descend at equal speed.

With respect to the heavenly bodies, it is found that their rate of motion is so regular as to never vary in the course of many years; and thus they illustrate the second principle of the doctrine of Inertia—that bodies will not come to rest of their own accord. Occasionally, however, the proximity of one planet to another will disturb each in its orbit. An instance of this occurred some years ago, which led to the discovery of the planet Neptune. M. Leverrier, in France, and Mr. Adams, of Cambridge, had noticed a disturbance of the motion of Uranus, and arguing on the principle that the inertia of that planet could not be affected except by an external force, they were led to imagine that another planet had, by virtue of its attraction, been the disturbing cause; and, eventually, they were rewarded by its discovery. This result may be adduced as a wonderful triumph of Mathematical and Physical Science, and also as an evidence of the exact and undeviating character of natural laws, in obedience to which, the planetary systems present no notable change in the lapse even of ages.

Numerous instances are daily occurring wherein the inertia of matter plays a prominent part. The jolting motion of a carriage passing over a rough road; the apparent projection of a passenger forward or backward, according as a boat in which he may be at rest is suddenly moved in the reverse direction, &c.—are cases wherein the body does not, by its inertia, partake of the motion, and therefore remains still. In the case of a collision on a railway, the passengers continue to move at the velocity they had already acquired, and are not able to bring themselves to rest: but the carriage in which they were travelling loses its motion, owing to the inertia of the object against which it had been impelled, and which opposes its further progress.

Having thus mentioned those properties which are common to every kind of matter, we proceed to inquire into the powers by which two or more masses mutually act on and attract each other. Before the time of Sir Isaac Newton, to whom is accorded the merit of having first proved the universal nature of the law of gravitation, many philosophers held the opinion that there was a great attractive force acting on all matter. Hooke, a contemporary of Newton, gave expression to such views, but in an unintelligible and enigmatic form. Newton, however, availed himself of some rough observations of the moon's revolution in her orbit, to test the idea of universal gravitation. By an acute intelligence, and deep mathematical acquirements, he was enabled, despite every obstacle, to make certain of that which had previously been mere conjecture. He not only proved the fact that masses mutually attract each other, but also demonstrated the amount of such attraction, and the variations to which it was subject at different distances of the attracting bodies.

GRAVITATION.—The attraction of gravitation, so far as our earth is concerned, may be defined as that force in obedience to which all bodies tend to fall towards its centre. This force varies according to the distance from the centre; and as the poles are about thirteen miles nearer to it than the equator, it follows that a body will weigh more at the poles than at the equator.

The amount of this variation is inversely as the square of the distance; or, more plainly, if any object be attracted with a force at any specified distance from the centre of the earth, at double the distance the force will be diminished to one-fourth; at three times the distance, to one ninth; and so on.

The amount of attractive force which two bodies in space can exert will be directly proportional to the mass of matter they contain; hence the greater mass will draw the smaller to it. But each has an attraction for the other; and if their masses do not greatly differ, they will, by their mutual attraction, remove each other from any supposed position they may have occupied, on coming within the sphere of each other's action. It is literally true, that the earth is attracted by every object raised from its surface, but as such bears no assignable proportion to the mass of the earth, the effect of course is infinitely small. If, however, a ball be attached to a flexible cord, and suspended near a mass of metal, the attraction of both the earth and metal will act on it, and, instead of hanging in a line perpendicular to the earth's surface, it will be drawn to one side. By comparing the attraction which a known mass of metal has, in causing a ball thus to diverge from the perpendicular, a rough idea of the density of the earth may be arrived at. This is, however, more perfectly ascertained by means of a pendulum, which, as it is continually falling towards the earth, when in motion, must necessarily vary in the number of its vibrations, according to its distance from the centre of the earth. At London, a pendulum of the length of 39.139 inches, vibrates sixty times per minute; whilst at the Poles, the number of vibrations would be much more numerous, and at the Equator they would be less.

By thus experimenting, it has been found that the weight of the earth is equal to that of about six globes of water of the same size, or, in other words, the earth weighs nearly six times as much as its own bulk of water.

One effect of the attraction of gravitation is, that bodies falling towards the surface of the earth, move towards it with an accelerated motion, that is, the nearer they approach the earth, the more space do they pass through in each second of time. In the case of a body being projected from the surface of the earth, its upward motion is gradually retarded until it comes to rest, and again returns to the earth, by virtue of the attraction of the latter. The acceleration and retardation here spoken of, are directly consequent of the law that the force of gravitation varies inversely as the square of the distance of the attracted from the attracting body. It has been found that a mass will fall, in one second of time, through a space of $16\frac{1}{10}$ feet; but, neglecting fractions, a general rule may be ennunciated—to the effect, that the space through which a body will fall during any number of seconds, may be ascertained by multiplying 16 feet by the square of the number of seconds of time during which it has fallen.

If, for instance, it were desired to know the depth of a mine, or the distance of the top of a tower from the ground, it would be only necessary to count the number of seconds of time which a stone takes in falling to the base; and by multiplying the square of the number of seconds by 16 feet, the depth sought for would be at once ascertained.

The rule just named gives only the total space through which a body would fall towards the earth during a given number of seconds. If it be desired to know the space passed through in each second, a different course must be adopted. It has been found, that by multiplying 16 feet successively by 1, 3, 5, 7, 9, &c., the space passed through in the first, second, third, fourth, fifth, &c., second is at once obtained. The reader will therefore perceive, that the *total* space passed through increases in geometrical progression, whilst the relative space in each second increases in an arithmetical ratio only. The following table will more fully explain the rules just laid down:—

Number of Seconds during which a body has fallen.	Space passed through during each Second.	Total space passed through,
1″	16 feet.	16 feet.
2″	48 ,,	64 ,,
3″	80 ,,	144 ,,
4″	112 ,,	256 ,,
5″	144 ,,	400 ,,
6″	176 ,,	576 ,,

The application of these interesting laws to the motions of the planets and other astronomical phenomena, will be fully dealt with under the section of Astronomy. The consideration of the cause of the tides will also fall under that head.

Having thus attempted to give a general idea of the force of gravitation, we pass on to consider the aggregation of atoms, and the causes of solidity, &c. It has already been remarked, that a mass is composed of very minute particles. These are brought and held together by what is called the attraction of cohesion.

COHESION.—This force, unlike gravitation, is only exercised at extremely small distances; and when particles are violently separated, they generally remain apart, owing to the loss of their cohesive power. The ordinary processes of pounding, cutting, cleaving, &c., are instances of cohesive attraction being destroyed between particles, or, at all events, they cause its temporary suspension. In some instances, however, parts of bodies may be reunited, as in the case of india-rubber, which, on being cut by a clean knife, may be joined together again by simply pressing the clean edges closely together. A leaden bullet, if divided by a sharp knife, may be re-formed by immediately bringing the surfaces together by means of a kind of twisting motion, assisted by pressure.

Highly polished surfaces will often adhere strongly if brought into close contact. Polished plate-glass affords an excellent illustration of this; for sometimes two sheets, if placed on each other, and having nothing between them, will adhere with such force as to prevent their separation. Finely polished steel surfaces often present similar results. Generally speaking, however, an extremely small distance is required to be attained before bodies will adhere; and hence the use of adhesive substances, such as glue and pitch, which, by touching the particles of two bodies in many places, produce a temporary cohesion of great force.

It may seem paradoxical, but at the same time it is true, that although the sense of touch leads us to imagine that we actually come in contact with a body, it is extremely rare that such an event takes place. If two pieces of convex glass, such as common lenses, are pressed together with great force by means of screws, there will still remain between them a plate of air, which, by its colour, indicates the distance still separating them. A needle resting on the surface of water, has round it a film of air which prevents the liquid from at all touching it. If the hand be pressed on any surface, there will generally exist three plates, which will prevent actual contact with it—namely, one of water, grease, and air. Again, if a little lycopodium, in powder, be cast on to the surface of some water, the hand may be thrust into the liquid without becoming moistened. Some of these, and similar, effects have been described as resulting from an active principle, which has been termed "repulsion;" but they are easily explained, by presuming that distance negatives the usual effect of cohesive attraction; indeed, the slightest film on the surfaces of the divided lead bullets above-named, will prevent their re-adhesion.

The different states of bodies, such as the solid, liquid, and gaseous, are caused, it is believed, by the repulsive power of heat. A solid may be supposed to have its particles close together. On the addition of heat thereto, its particles are at once driven farther apart, and a fluid is produced. By a still further application of heat, the particles of the fluid may be separated to a greater distance, and a gas or vapour will be produced. The most common illustration of these three separate states being found in one body, is that of water, which may be successively a solid as ice, a fluid as water, and a gas in the form of vapour or steam.

Masses may be reunited, after division, by various means; solution and crystallisation being those most commonly employed. Sugar, for example, may be powdered, and no pressure will reunite the particles. On being dissolved in water, the different parts are aggregated, and the solid mass may be restored. Under the section on Crystallography, this mode of inducing cohesive attraction will be fully explained.

CHEMICAL, ELECTRICAL, and MAGNETIC attraction will necessarily be spoken of under the respective branches of Science to which they relate. It will therefore be sufficient to state that they exercise a varied influence on, and modify or control, the form and condition of bodies. The former of these forces has a universal effect throughout nature; whilst the influence of Magnetism is, comparatively speaking, restricted to the metal iron, and its compounds.

CAPILLARY ATTRACTION.—This force seems to be a modification of that of cohesion, and is manifested whenever a liquid is in contact with solids, which are placed at small distances from each other. On dipping a narrow glass tube into water, it will be found that the fluid will rise higher inside the tube than the general level of the aqueous surface. A lump of sugar absorbs and raises above its level any water in which it may be placed. This force has an astonishing effect both on animal and vegetable economy. By its action the sap is conveyed from the root of the plant or tree to the highest branches; and, generally speaking, liquids are raised by this force for a vast number of purposes in nature. To this end the pores or interstices of bodies highly contribute: and thus, whether we regard the cells of animal and vegetable structure, or the particles of sand, earth, loam, &c., this comparatively unobserved but constantly acting force, is one of the chief agents in producing an infinite variety of effects. In daily life, capillary attraction is constantly employed: as, for instance, in the conveyance of oil in lamps by the wick; in the absorption of perspiration by clothing; and in other ways too numerous to mention.

We have hitherto restricted our remarks to those properties of matter and forces in nature which are properly called universal, because we can conceive of no body which can exist unaffected by them. There are, however, others to which we must direct attention; because, although not partaken of so generally, they are discovered in most of the objects to which the researches of philosophers are directed. It will be found that some of these properties are characteristic of the body possessing them; but in others, these properties may vanish when the state of the body possessing them, is varied by the action of heat and other forces.

ELASTICITY is that property by virtue of which bodies regain a form which they had temporarily lost. The effect of Elasticity is produced when two other properties, COMPRESSIBILITY and EXPANSIBILITY, are called into exercise. Air, for instance, when *compressed*, will at once *expand* on the pressure being removed; hence air is called an *elastic* body. Some masses may be compressed, and will not regain entirely their previous form; but a perfect elastic body is one which will oscillate between its original, a larger, and smaller form—eventually, however, regaining its previous size. A common ivory billiard-ball is one of the best illustrations of this class of bodies, and wet clay may be adduced as an instance of those of an opposite kind. All gases are highly elastic, and, owing to atmospheric changes, are perpetually undergoing alteration of bulk. Liquids are sparingly so; and, in fact, seem to form an exception to these laws; but, by careful experiments, it has been ascertained that water is elastic; for, having been compressed by enormous pressure, it will regain its previous volume on the pressure being removed.

The mind at once recurs to the numerous applications of the elasticity of different materials. The springs of carriages, the buffers of the railway car, the passage of gas through the mains conveying it, the production of wind, the main-springs of clocks and watches, &c.—all are instances wherein elasticity plays an active part. But, perhaps, the most interesting object of this force is involved in the arrangement of the different parts of the human body; which, by the elasticity of their separate processes, permit any kind of motion to be safely undertaken, that would certainly destroy the construction of the most perfect of human mechanical productions.

SPECIFIC GRAVITY.—A relative property of bodies is that called Specific Gravity; and the term is employed to express the fact that the same bulk of different substances varies in weight. Thus air weighs about $\frac{1}{800}$th part of its bulk of water; whilst iron weighs more than seven times as much as an equal bulk of water. The various means used for ascertaining the relative weights, called Specific Gravities, will be described as required in the progress of the work—an arrangement which will assist the student in learning the valuable application of the law, more especially in reference to the processes of the chemist, the weight of machinery, &c.

CENTRE OF GRAVITY.—This term is used to point out that part of a body wherein all the forces acting on it are in equilibrium. In a globe or sphere made of materials of one kind only, the centre of gravity would be at the centre of the body: hence, if the sphere were suspended by that centre, all its parts would hang round it at rest. If, however, we imagine a sphere to be made partly of wood and of lead, the specific gravity of the metal is so much greater than that of the wood, that the lead, if not placed exactly in the centre of the sphere, would have the centre of gravity somewhere in itself. The common toy, the Chinese tumbler, is constructed so that its centre of gravity shall be at the lower part. The centre of gravity of an egg is so placed, that it will, if left to itself, lay sideways on a level surface. If, however, its contents are violently shaken, the yolk will settle to one end, and the egg may easily thus be made to stand upright, because its centre of gravity has been shifted from its previous position near the centre. The applications of the law will be fully considered under the head of Mechanics: it may, however, be interesting to point out here some cases where its action is prominent. In walking, we are continually shifting the centre of gravity of our bodies: in the construction of railways, the lines are so laid as that, in curves, one rail shall be higher than another, so as to prevent the train running off the line; and, in loading ships, care is taken that the cargo shall be so distributed as that the centre of gravity of the vessel shall be in the best position to insure speed and safety. When a vessel is required to sail from one port to another without cargo, a quantity of coarse gravel, called "ballast," is cast into the hold, which thus maintains the centre of gravity low down in the hull.

Having thus attempted to give an introductory view of properties and forces to which all matter is subject, we proceed to detail those branches of Science which take cognizance of special forces, qualities, and phenomena; and in so doing, we shall confine our attention to those only which will be introduced and explained in these volumes, dealing with them in the order in which it is proposed to arrange them.

It has already been stated that force is required to set matter in motion; but, beside the forces to which reference has already been made, and which affect only the external condition of matter, there are others which can modify and change it in so many ways, as to produce results which are of the highest importance in animal and vegetable existence.

HEAT.—The first which we shall notice is the power or agent called Heat—one of the most active and necessary in creation. We shall have to examine its effects on matter, in the solid, liquid, and gaseous state; its production, conveyance or conduction; and other facts relating to its diffusion and general agency. It may here be remarked, that the term CALORIC is often used instead of heat, as being more in accordance with scientific phraseology. Natural phenomena, such as Wind, Rain, Dew, Evaporation, &c., will be dealt with under this head; and the varied applications of heat, and the instruments used for its measurement, such as the Thermometer, will be fully described.

LIGHT.—Under the head of Light, a vast variety of interesting phenomena arrange themselves; such as colour, reflection, refraction, polarisation, &c. Photography, as one of the most interesting of the numerous applications of Science, will claim an extended notice; and ample directions will be given, so as to assist the reader in the pursuit of the art. Optical Instruments, employed in scientific research, and for social and amusing purposes, will be explained, both with respect to their construction and use. Among these will be included, Telescopes, Microscopes of all kinds, the Magic Lantern and Dissolving Views, Cameras, Stereoscopes, Polariscopes, &c. The production of Artificial Light will also be extensively illustrated. In this branch of philosophical research some most interesting discoveries have recently been made by Messrs. Bunsen and Kirchkoff, who, by means of the spectrum analysis, have opened out an entirely new field in Chemical and Optical Science.

ELECTRICITY.—No branch of Science has made, during the present century, such rapid strides as Electricity. Its various divisions of Frictional and Voltaic Electricity will be examined, together with numerous natural phenomena arising from their agency. Electro-Chemistry, Electrotyping, Plating, and Gilding, naturally fall under this section; and extended details of these processes will be afforded.

MAGNETISM.—To the existence of this force we are indebted for the mariner's compass, whose variation will require special notice. Terrestrial Magnetism and Dia-Magnetism will be investigated, and the leading facts and experiments on these subjects will be introduced. The action of the material and cargo of ships on the compass will be explained, so far as modern Science has brought light on that intricate subject.

ELECTRO-MAGNETISM.—This branch of Science is of very recent origin; and its chief application, the electric telegraph, has made it, so far, the most popularly known of any. The production of magnetic effects in soft iron, the mutual action of Electric and Magnetic Currents, the divergence of the Magnetic Needle, and the various applications of these effects, such as the Electric Telegraph, both on land and through water, together with Electro-Magnetic Machines, will be found in this section. Ruhmkorf's new Induction Coil, and various experiments with it, will be explained.

ACOUSTICS.—The four agents, Heat, Light, Electricity, and Magnetism, are at present supposed to be produced by motion of an undulatory nature; and much analogy exists between them and the production of sound. Under the head of ACOUSTICS, this connection will be considered; together with the conveyance and reflection of Sound, Echoes, Musical Instruments, and other allied subjects.

CHEMISTRY.—The most casual observation will at once suggest that there must exist a vast variety of substances in nature, having qualities greatly differing from each other. It is the object of Chemistry to discover these qualities, and to examine their mutual relationship. In dealing with this branch of Science, the chemical history of Inorganic Bodies will be first considered. The Chemistry of Life, both vegetable and animal, Agricultural Chemistry, and Chemical Analysis, will follow in order; and the subject will be made complete by an extended notice of the numerous applications of chemistry employed in the arts, manufactures, and in mining and metallurgy.

MATHEMATICS.—The object of Mathematical Science is to point out the different relations of Number, Time, and Space. Arithmetic, Algebra, Logarithms, and Logarithmic Tables of Natural Numbers; Geometry, Plane and Spherical; Trigonometry; and the application of these, under the heads of Practical Geometry and Mensuration, will be all fully investigated in this section: and each branch will be so treated as to enable the student to master the majority of problems which occur in the application of Mathematics to the investigations of Physical Science. Every endeavour will be made to combine simplicity of expression with scientific instruction.

MECHANICAL PHILOSOPHY, or APPLIED MATHEMATICS.—Under the head MECHANICS, the Laws of Motion and Force, as applied to Machinery, will be first considered; with mechanical contrivances for economising labour, or for producing motive power, including Steam-Engines, &c. Implements of husbandry and trade, and other similar mechanical inventions, will be fully described; and their essential peculiarities also pointed out. Rules for calculating the power of engines, the weight of machinery, its regulation, and other interesting facts, will be included, so as to make this section of value to the practical man.

HYDROSTATICS and HYDRAULICS.—The different fluids which are generally typified by water; the laws which govern them when at rest or in motion; the application of these laws, as in Water-Wheels, &c.; the flow of Water through pipes; the construction of Canals and Reservoirs; the Hydraulic Press, and many allied matters, will be dealt with under this head.

PNEUMATICS.—The laws which govern air and other gases are generally included in this branch of Science. Beside explaining the causes of many atmospheric phenomena, we shall here give descriptions of the Barometer, Pumps, Air-Engines, and other inventions which depend on the application of the laws of air or gasiform bodies.

ASTRONOMY.—The consideration of the subjects to which we have hitherto alluded, necessarily attaches the mind to objects of terrestrial interest. In the study of Astronomy, we are led beyond all mundane influence, and seem to take so high a stand in nature as to be enabled to have an extended survey of the works of the Creator. For sublimity of subject and range of observation, Astronomy stands immeasurably beyond every other branch of Science. Even a superficial view of its truths is deeply interesting to the intelligent mind. But our object will extend further. It will be our endeavour to give an insight into those laws by which the constitution and motion of the Heavenly Bodies are governed. Whilst a popular description of Astronomical Science will be afforded, the mathematical student will have an opportunity of investigating the truths and bases on which the leading theories of this noble branch of Science are founded. It is impossible to enumerate here the varied matters which we shall have to speak of. The Sun, the Planets, the Earth, and Moon; their motions in their orbits and on their axes; the causes of the Tides, of Eclipses; the nature and motion of Comets; the Constellations and Fixed Stars, &c., will be dealt with, so as to interest both the general and advanced reader; and in a way which, we trust, will add the element of intelligence to the natural admiration which all feel when they "consider the heavens," the handiwork of GOD.

NAVIGATION and NAUTICAL ASTRONOMY.—Nothing is of greater importance to the navigator than a knowledge of Astronomy. By it he is enabled to trace his path on the sea with a certainty which seems truly marvellous. The heavenly bodies are as celestial lighthouses to him; and, by observing their positions, he is enabled to calculate his exact place on the surface of the earth. The subject will be dealt with in an essentially practical manner; and ample rules will be given for calculating, arithmetically and by logarithms, the leading problems of this branch of Science; such as Latitude, Longitude, errors caused by Refraction, Departures, Courses, and allied subjects. The relations between Astronomy and Navigation will thus be fully pointed out, and varied practical matter will also be introduced in this section.

With some of the subjects named above, tables of various kinds will be required; and these have been accordingly supplied in each section, so that the student will have no occasion to refer to other works.

METEOROLOGY.—This interesting and almost new branch of Natural Science, gives an explanation of the various phenomena which occur in our atmosphere. Amongst these may be named—Wind, Water-Spouts, Rain, Hail, Snow, Thunder and Lightning, the Aurora Borealis, and Shooting Stars, Dew, Moisture, Evaporation, Clouds, &c. We shall include an ample description of the different modes adopted for the purpose of observing and registering atmospheric changes, and give directions for ascertaining the approach of storms, cyclones, &c.; referring also to the late efforts of the British government, to diffuse this valuable information amongst seafaring persons. The simplest and most economical mode of pursuing private observations will claim our attention, and special instructions will be given to assist those who are desirous of undertaking that interesting occupation.

From the brief epitome thus presented, it will be observed, that the division of our work treating on Natural Philosophy, will include the different branches of Science which share the description of the laws of inanimate nature. In our progress, a large variety of experiments will be introduced, which will enable the reader to test the truth of the principles or assertions which are laid down. As we have previously remarked, Observation and Experiment are the bases of sound philosophy; and, as a rule, nothing should be assumed but what can be proved. Our endeavour will be to avoid, as far as possible, the use of technical phraseology; and where such is absolutely necessary, sufficient explanations of the terms so employed will be given, so that the reader will not need to refer to other works for explanation.

In the second division of the work we shall deal exclusively with those branches of Science which relate to the laws of Organised Bodies. The student will find that his previously acquired knowledge of Experimental Philosophy will be called into practical exercise when he enters into the examination of the phenomena of animal and vegetable life. His acquaintance with Inorganic Chemistry will enable him to examine the variety of substances described in the section on Mineralogy; and, when collecting specimens, he will find the great value which accrues from the application of chemical analysis and the use of the blow-pipe, in arriving at a knowledge of the constituents of mineral substances. We may here observe, that immense sums have been wasted by otherwise intelligent individuals, who, having discovered what appeared at first sight to be ores of great value, in previously unknown positions, have not been able to apply the laws of Chemical and Geological Science in verification of their opinions. Thus, it has been proposed to search for coal in some parts of Kent and Surrey. The writer was once seriously informed by a lady that she had discovered a "silver mine" on her estate in Essex; and he can call to mind several instances where search has been made in different parts of England and Scotland for lead, copper, &c., which any geologist would at once have pronounced as sure to prove futile, and with a certainty which would leave no room for conjecture.

The arrangement of the division on Natural Science, will include Comparative Anatomy, Zoology, Ethnology, Botany, Crystallography, Mineralogy, Physical Geography, and Geology; and we shall take them in the order we have named. We do so, because a knowledge of Comparative Anatomy, Zoology, and Botany, is essential to the student in enabling him to arrange and classify the fossils which form the key-stone of all our geological discoveries. Any person well acquainted with these branches of Natural Science, will have no difficulty in at once ascertaining the period at which any strata of the earth's crust he may meet with has been formed. Indeed, fossils have been expressively called the "medals of creation."

Under the head of Comparative Anatomy, we shall describe the form, size, and number of the bones which are found in skeletons of different organised beings. This branch of Natural Science is of the deepest interest to every lover of nature; and to Professor Owen (the Cuvier of Great Britain) we owe a vast accession of knowledge respecting the relationship which exists between each class of extinct and living species.

The object of Ethnology is to trace the characteristics of what have been called the "races" of men. With respect to this term, Dr. Latham well remarks, "that all the varieties of man are referable to a single species;" and, for that reason, he defines Ethnology as the "Science of Varieties."

Under the head of Zoology, it will be our duty to trace the Natural History of animal creatures, from the lowest to the highest species. Their production, growth, characteristics, will be inquired into; and the subject will be made of popular interest by the introduction of anecdotes, illustrating the instinct of many of the Mammalia, &c.

From Animal Life we descend to that of the Vegetable Kingdom. In this, with but trifling exceptions, we lose all sign of the power of locomotion. We perceive a cellular structure, and the circulation of sap; each of which is analogous to the bone and blood of the animal. The student who has not already become acquainted with Botany, will at first imagine that the variety of vegetable productions is like that of the mineral kingdom, almost infinite. But Botany, like Chemistry, systematises our observations: and thus, as we find but sixty or seventy elementary bodies by the aid of chemical analysis; so, by using the arrangements which Botanical Science affords us, we are enabled to arrive at a classification of every tree, plant, and flower.

Leaving all trace of life, we descend to the lowest rank in creative results, but still find abundant objects for study and reflection. Crystallography opens out an astonishing evidence of design, by showing that inanimate substances have specified forms of their own. Thus it matters not in what part of the world we find a grain of quartz, nitre, or common salt—we shall discover that an exact and undeviating crystalline form is possessed by it. We shall find a knowledge of Geometry of essential value in this branch of our studies; indeed, we shall do no violence to truth, if we call Crystallography the geometry of inanimate matter.

Having mastered the details of the last subject, we shall be enabled to study with advantage the facts of Mineralogy—a subject of great interest, and of the highest importance in an economical and commercial point of view. This section will afford a detailed description of most known minerals; the places in which they have been discovered; their crystallographic forms, &c. Those of our readers who may have access to the British Museum, will find an account of nearly all the minerals contained in the collections, at that institution.

GEOLOGY—the last subject on which we shall treat—has for its object the explanation of the various causes which have changed or modified the appearance and nature of the crust of our earth. Of all branches of Science, except Astronomy, this has been a source of the fiercest contention on the part of speculatists of every school. The zealous but hasty Christian philosopher has called in its facts to prove his views; and the sceptic has employed the same facts for a diametrically opposite purpose. The philosophers of one school have, on certain data, "proved" theories which their opponents have as vigorously "disproved" by the same means. We might remark on this subject to our readers, that if there be any branch of Science calling for patient, calm, and philosophic thought, it is this. The imagination, at all times, unless chained by the iron fetters of sound reason, will rush violently to conclusions; and hence the bitter denunciations which geological opponents have hurled on each other. If, however, the student will follow carefully the laws of rigid induction, he cannot avoid arriving at the truth; and in his observations he will assuredly find

"Sermons in stones, and good in everything."

Throughout the divisions of the work, every endeavour will be made to render each subject as complete as possible. Those who have already advanced in scientific pursuits, will find formulæ and facts, conveying full information in each department; and, where necessary, mathematical demonstrations will be freely employed. The practical engineer, and others engaged in like pursuits, will be enabled to trace the various steps between Abstract Science and those extensive ramifications through which Experimental Philosophy and Applied Mechanics spread their influence. The general reader will, it is hoped, gather information which, whilst strictly philosophical, will be, by a little attention, easily arrived at; and, as far as possible, the difficulties which naturally present themselves in every work on Science aiming at completeness, will be modified by the use of concise description, and illustrative experiments. In conclusion, we have to express the hope that, although many omissions and shortcomings must necessarily occur in our pages, the object which has been constantly held in view—that of assisting the reader to an intelligent and practical acquaintance with the laws of Nature, and their general applications—may yet be, in some measure, attained.

Having thus laid the foundation—if we may so say—of our work, and having given a general view of its arrangement, it may be useful to our readers to place before them, in a tabular form, the various subjects to which we have alluded. They have been so arranged as to conduct the student, from the most elementary principles, to a knowledge of each branch of Science into which the study of Nature is divided, according to the present system of philosophy. Without attempting to claim for our method any special advantage beyond that afforded by others, we venture to suggest that those who follow it will be enabled gradually to advance from comparatively well-known to more abstruse subjects, in such a manner, as that they may use the knowledge acquired in each step for the elucidation of that which has to follow.

The entire work is composed of two great divisions—the first relating simply to matter and forces; the second to matter and forces as connected with vitality, &c. The sub-divisions connect allied subjects; whilst the sections, into which each volume is divided, serve to render reference easy. They also separate the comparatively minor details, by which each sub-division is characterised, in a manner which is at once convenient and philosophical.

DIVISION I.—VOLUME I.—EMBRACING EXPERIMENTAL, CHEMICAL, MATHEMATICAL, AND MECHANICAL PHILOSOPHY.

SUB-DIVISION I.—EXPERIMENTAL PHILOSOPHY—UNDULATORY FORCES.

SECTION I.—HEAT.
" II.—LIGHT.
" III.—ELECTRICITY.
SECTION IV.—MAGNETISM, ELECTRO-MAGNETISM, AND DIA-MAGNETISM.
" V.—ACOUSTICS.

SUB-DIVISION II.—CHEMICAL PHILOSOPHY.

SECTION VI.—INORGANIC AND ORGANIC CHEMISTRY.

SUB-DIVISION III.—MATHEMATICAL PHILOSOPHY.

SECTION VII.—MATHEMATICS, INCLUDING ARITHMETIC, ALGEBRA, GEOMETRY, TRIGONOMETRY, ETC.

SUB-DIVISION IV.—MECHANICAL PHILOSOPHY.

SECTION VIII.—STATICS, DYNAMICS, HYDROSTATICS, PNEUMATICS, ETC.
" IX.—APPLIED MECHANICS.
SECTION X.—ASTRONOMY.
" XI.—NAVIGATION AND NAUTICAL ASTRONOMY.
" XII.—METEOROLOGY AND CLIMATOLOGY.

DIVISION II.—VOLUME II.—NATURAL SCIENCE.

SUB-DIVISION I.—THE ANIMAL KINGDOM.

SECTION I.—COMPARATIVE PHYSIOLOGY.
" II.—COMPARATIVE ANATOMY AND OSTEOLOGY.
SECTION III.—ZOOLOGY.
" IV.—ETHNOLOGY.

SUB-DIVISION II.—THE VEGETABLE KINGDOM.

SECTION V.—BOTANY, DESCRIPTIVE AND SYSTEMATIC.—ECONOMIC BOTANY.

SUB-DIVISION III.—THE MINERAL KINGDOM.

SECTION VI.—CRYSTALLOGRAPHY.
" VII.—MINERALOGY.
SECTION VIII.—GEOGRAPHY.
" IX. & X.—GEOLOGY.

We have already explained those general laws to which matter is obedient, whatever kind, form, or state it may be possessed of; and, with this general introduction, we conceive our readers will be quite prepared to commence the study of any of the sections. Some little difficulty, however, may be presented in the first subdivision—viz., that which treats on Experimental Philosophy, in connection with the Undulatory Forces; and we shall, therefore, endeavour to smooth the way of the student by some general remarks on their nature, laws, and correlation. As we shall see in our progress, the term is comparatively new, and has been applied to Heat, Light, &c., on account of certain theoretical views which are maintained at the present day. By means of the theory referred to, the various phenomena of each force can be viewed in a definite relation to those of the rest, and thus great assistance is rendered to the philosopher in generalising on, and to the student in acquiring, the facts which they present to our observation.

THE PHENOMENA AND LAWS OF THE UNDULATORY FORCES.

The most indifferent observer of natural phenomena cannot fail to notice the variety which presents itself on every hand; and we can scarcely imagine a more interesting occupation for an intellectual creature, than to trace the causes of those changes which are thus continually afforded us. In no department of Natural Science is there any possibility of disappointment; in fact, wherever we attempt the investigation of those laws which govern Creation, order, beauty, and precision are prominent characteristics.

It, however, is impossible that we can suddenly appreciate the perfection which Philosophy discloses to us, in all the arrangements and sequences of prime causes, unless we enter into their study with a determination to put aside every preconceived notion, and to be taught by the lessons which are but slowly unfolded to us. To all but the humble philosopher, Nature is a sealed book; but to those who enter her kingdom as little children, a storehouse of knowledge and enjoyment is at once opened.

This humility, however, is only arrived at after much experience, because there is an idea entertained by every tyro in Science, that he is at once capable of understanding the assumed simplicity of natural laws. The true man of Science has to arrive at this by slow degrees; and, after achieving a position which, to ordinary minds, seems to be one of the highest importance, he so far learns his own ignorance as to doubt whether he has attained to any knowledge. In the words of an eminent living philosopher, " I once thought that I knew all that was to be known of Science; but the longer I live, the less I seem to know of it."

These remarks are fully borne out by the fact, that all our discoveries of the causes of most of the effects observed in nature, have been arrived at by the most difficult and laborious processes. It matters not what department of Science we choose as illustrative of this truth. In every branch observation has frequently been baffled, the process of induction has been delayed, and the establishment of an adequate theory has been effected only by the most extended investigations, after apparently accurate inductions have undergone the sifting process of many independent and occasionally hostile minds.

If, however, we study the result of such labours, we cannot but admire the perseverance which has been employed, and must rejoice that human intellect holds so proud a station as that of being able, to a small extent, to understand those laws which God has impressed on all His works. Even beyond this, we now reap the fruit of the works of those who in former days devoted themselves to investigate some of the most intricate of the operations in nature. The labours of a Newton and a Leibnitz are now the very bases of our national prosperity; for without the results which those great men first opened out, our position as a maritime people would yet have to be won.

In many instances, the most valuable additions to scientific stores have been accidentally met with. We must not, however, forget, that while so-called "accidents" occur to every observer, they are only made use of by those whose minds are prepared to reflect on, and examine, any new appearance which may attract their attention. The discovery of the polarisation of light, and of electricity evolved by chemical action, are instances of the most common occurrences being turned to philosophic purposes. Every one must have observed that the light of the sun produces most beautiful colours when reflected from a thin film of oil floating on water; but it required the penetrative genius of Newton to explain their cause: and, since his time, the most talented intellects of the day have never ceased to expand the ideas whose germ Sir Isaac first gave in his experiments with the thin plates of light on the soap-bubble, and those produced between two pieces of glass closely pressed together.

In reference to processes in various kinds of manufacture, it is often found that great progress has been effected entirely independent of accurate scientific information; but such progress has been necessarily slow, owing to the want of knowledge on the part of those who had to superintend the operations. At the present time, however, a fresh discovery is scarcely made in any branch of scientific research, before its applications are instantly effected; and, possibly, the two most remarkable instances on record of this nature, are those of the Electric Telegraph and Photography—the two greatest marvels of our age.

We may, as illustrating this position, adduce the state of the glass manufacture during the Roman era, and that which it occupies at this moment. In the time of Nero a glass vessel cost an almost fabulous price, whilst now the meanest utensil is made of that material. This, and many such results, have accrued solely through a knowledge of certain natural laws being first obtained, and afterwards applied by intelligent and scientific manipulators.

Nearly all the most remarkable and beneficial inventions which have been produced during the last two centuries, have been the result of deep researches into the action of those forces which have been termed imponderable agents, or, as they are now called, " Undulatory Forces." Thus, in the applications of Heat, Light, Electricity, and Magnetism, we have remarkable illustrations of the value which is involved in the extended study of abstract Science, antecedent to applying the results so obtained in a practical form. By the study of the laws of latent heat, Dr. Black and James Watt have presented us with that mightiest of human contrivances—the Steam-Engine.

Our immense riches in iron and coal were as dross until extensive arrangements were constructed, by means of which intense and long-continued heat could be produced in our furnaces. To the earlier investigators of the laws of the refraction of light, from the time of Galileo, we are indebted for the accurate construction of our telescopes, by means of which we can penetrate into space, and discover the laws of planetary motion, which, when applied by the navigator, are of the utmost commercial importance to us. By means of the microscope, as another application of the laws of light, we are enabled to detect differences of nature, quality, &c., utterly unapproachable by the naked eye. There is perhaps no law of nature which has so magnificent a range as that of the refraction of light, for in its minute application we may detect the presence of individual insects, millions of which may be crowded into a space less than the size of a pin's point; and, in the next moment, may view by its agency groups of stars—to count which, is beyond the power of the most accomplished astronomer. Again, the generalisation of this law of light is truly marvellous; for we observe that the delicate colour of the flower, the gorgeous plumage of tropical birds, the colours of the rainbow, and the infinite variety of colours seen throughout nature, are all produced by this one cause. Proceeding to the polarisation of light, we enter into one of the most fascinating of all scientific pursuits, and are enabled to detect the most brilliant and varied appearances which the imagination can depict, in bodies which, to the unassisted eye, seem utterly destitute of beauty.

Turning to another of the imponderable forces—Electricity—we find an agent which, although almost always unperceived by our senses, is, nevertheless, only second to light in its universality: at one moment we find its presence manifested in the vivid flash of lightning; whilst, at the same instant, it is all but the animating power of our existence, and is coursing unperceived through our nerves and muscles. In its applications, we have it at times passing through wires, and enabling us, by its heating effects, to destroy masses of rocks as with the power of a giant; and yet, at our command, it silently travels by the path we choose for it, until, vibrating the little compass-needle, it conveys instantaneously the expression of our wishes from one extremity of the world to the other—commanding the march of hostile armies, or conveying words of peace and good-will towards men.

With respect to Magnetism, we need scarcely remind the reader, that, to an application of its laws, we are indebted for the mariner's compass, by which our sailors may steer safely by day or night across the otherwise trackless ocean. In the deepest darkness, without a star to be seen, in storm and tempest, the helmsman keeping his eye on the oscillation of the needle, progresses boldly on his voyage, and pursues his course as free from error as if a cloud of fire directed his path. With what a noble contrast does a modern voyage stand out when compared with that of Ulysses, who, coasting round shore after shore in search of his beloved Ithaca, had nothing to guide him in the absence of a clear sky. Besides the mariner's compass, there are various facts of the most interesting nature, which have been brought to light by the researches of Faraday and others, as some of the effects of the magnetic force. These have been arranged under the term Dia-Magnetism; and we learn that nearly every substance in nature can be made susceptible of the magnetic force, and not iron alone, as had previously been imagined. We must, however, not be misunderstood as referring here to that pseudo-scientific nonsense termed Mesmerism, &c., which is merely the product of the ignorance and evil design of some men. The effect to which we refer, and of which we shall fully treat hereafter, is the result of the agency of natural laws, which have been carefully studied both as to cause and effect, by men whose names alone are a guarantee for truth and accuracy.

We have hitherto refrained from mentioning the connection which each of the imponderable agents have with others; and the subject, of course, can only be dealt with here in the most superficial manner. It will answer our purpose, until we treat more fully on the matter in future pages, to remark, that each of the four forces, Heat, Light, Electricity, and Magnetism, are mutually producible; or, in other words, the presence of either agent may be, or generally is, united with that of another. For instance, by heating a substance to a high temperature, it becomes red or white hot, emitting rays of light just in proportion to the intensity of heat employed. By heating a few bars of antimony and bismuth, arranged in a peculiar manner, electricity and magnetism may be produced. Again, electricity continually produces heat, light, and magnetism, during its progress by conductors. Magnetism not only produces electricity, &c., but will, under certain circumstances, magnetise a ray of light; whilst a ray of light can be used to render a sewing-needle magnetic.

We may remark, that with respect to all these forces, motion of some kind is necessary to their evolution; and that, in most cases, they exist in what is called a *latent* state. Thus, for instance, the well-known article of food, sugar, may easily be made to afford heat, light, and electricity in a perceptible state, by means of chemical and mechanical action. It is also remarkable, that whenever any of these forces is set free, motion is, generally speaking, communicated to matter, as in heating a body, which causes its parts to separate or expand. Motion and these forces have therefore a mutual relation; and philosophers have endeavoured to account for the existence of the imponderable agents, and for the phenomena they produce, by supposing that an "ether," which is presumed to be far more rare than matter, and to exist in the pores of bodies, is put into motion, and by its undulations, gives rise to the varied effects we observe when heat, light, &c., become evident to our senses. Others have supposed, that each of these forces is owing to the emanation of a peculiar kind of matter from bodies, which, by radiating from any object, produces heating, lighting, and electric effects. We shall, however, not stop to discuss either of these theories, because we must take them in detail hereafter, and endeavour to satisfy, as far as possible, in the present state of scientific knowledge, all enquiries which may be made on this interesting question.

We have stated, that most of the imponderable agents are mutually producible; but we must add, that between two of them a most remarkable analogy exists in some respects. We refer to light and heat, the rays of which can be both refracted, reflected, and polarised. Thus, if a heated or luminous body be placed in the focus of a concave mirror, the rays of either force may be reflected from one, and received on another mirror placed at a considerable distance from the first. The phenomena, as produced by either force, are found to be obedient to the same laws; and the only difference we can detect, is in the nature or speciality of the force under examination.

By the term "refraction," we mean that the rays of either heat or light are bent out of their straight course when passing from a rare into a dense medium, or *vice versâ*. A very simple illustration of refraction is witnessed when a stick is put obliquely into a vessel containing water. The stick will appear bent, or broken, owing to the rays of light which pass from it being bent or refracted from a straight line. In a similar manner, if light is made to pass through a piece of glass of a triangular shape, such as a prism, the ray is refracted, and seven beautiful colours are produced. A ray of heat may be refracted or broken up by passing it through a prism of rock-crystal; and although, of course, no colours are visible to the eye of the observer, still effects exactly like those produced by the glass prism on light are at once afforded.

The effects of polarisation are not so easily understood without a lengthened description, which we shall give in its proper place. We may, however, state, that when a ray of light is passed through, or reflected from, a bundle of glass plates, or a piece of tourmalin, it is divided into two parts, one of which proceeds onwards, and the other is deflected at a certain angle. Our description would be more scientific, if we were to say that one ray is transmitted and the other reflected. The very same result happens to heat, if its rays are treated in a similar manner.

For these and many other reasons, we may arrive at the conclusion, that heat and light proceed from the same cause, modified by circumstances with which we are at present but slightly acquainted. This assumption, though most likely true, is not based, however, on an unexceptional foundation.

Each of the forces of which we are now speaking, are termed central or radial, because their effects are observed to extend in straight lines from a centre. As we shall subsequently prove, their intensity diminishes as the square of the distance from the source; and having any data of the amount of force first excited, its intensity becomes a matter of easy measurement.

With respect to the speed with which these forces travel, little is known, except in reference to light; and here we may speak with tolerable certainty. By observing the eclipses of Jupiter's satellites, it is found that their light does not appear so soon after an obscuration as it should do, according to exact astronomical calculations. Now, as the latter are so accurate as not to vary in many instances to the extent of a second, even if the event predicted shall be months after being calculated in coming to pass; and as the distance of Jupiter from the earth, and other data, are well known, it requires little stretch of the imagination to guess, that the error of observation is due to the length of time required for the light of the satellite to reach the earth after it had passed the solid body of its planet. Thus we judge that light travels at the rate of about 200,000 miles per second. To familiarise this to the mind, we may add, that a ray of light would pass round the earth eight times in one second; that it requires but one second of time for light to pass from the moon to the earth; and if the sun could suddenly be obscured on the surface of its luminous part, and again exposed, we should not perceive its light, after first losing it, for the space of about eight minutes.

We have no means of ascertaining the rate at which heat travels, except when associated with light, as in the rays of the sun; and, so far, it has been judged that heat and light travel at an equal speed.

Electricity seems to travel at a speed which varies according to the conductor through which it passes. In the earlier works on this subject, an extraordinary rate was assigned; but recent experiments by no means countenance the idea. There are so many interfering causes, as to leave the best-tried results uncertain. As far as our present knowledge goes, it would seem that, in a conductor 3,000 miles long, the electric effect is observed at its extremity in about a second of time. There is, however, a very singular result perceived when a current of voltaic electricity is sent through a very long wire. Instead of the effect being instantaneous, the delivery of the current is protracted just in proportion to the length of the conductor, after the first sign of the presence of the current is manifested. The electricity seems, in fact, to have lost its instantaneous, and to have acquired a gradual, mode of evidencing its presence.

Our means of producing magnetic effects are so small, as to preclude the chance of measuring the rate at which they are propagated. The comparatively small distance at which magnetism is perceptible from its sources in our experiments, and the impossibility of our cutting off the effects of terrestrial magnetism, present insuperable difficulties in arriving at a knowledge of the speed of the magnetic force.

After discussing the different laws which research has opened out to us, it will be our duty to present, in the following pages, some outlines of the applications of which the imponderable agents are susceptible, whether in respect to natural occurrences, or for social, economical, and domestic purposes. It will be our endeavour to impress on the minds of our readers the truths of the different branches of Science; and, presuming that those have been mastered, their varied applications will necessarily become interesting and valuable. And here we have a wide field opened for contemplation. There is scarcely a circumstance, or an object of daily life in our time, but which points to Science as having something to do with it.

Let us, for instance, take each force in the order in which we have hitherto spoken. To Heat we are indebted for our steam-engines, our metallurgical processes, the infinite variety of manufactures which employ the industrial population of our country, and also for the comforts, conveniences, and vital necessities of our social existence. Of some of these applications we shall speak under the head of Steam, and Warming and Ventilation. Many others we must defer to our Chemical section. The natural phenomena dependent on heat—such as Volcanic Agency, the heat of the Sun, Climate, &c.—we shall enter into in the subject of Terrestrial Heat, on which we shall have still further to expand when we treat on Meteorology.

The Applications of Light—such as the Cause of Colour, Optical Instruments, Artificial Illumination, Photography, &c.—will immediately follow our consideration of the Laws of Optics; and thus what has been by many considered to be a comparatively difficult subject, will be found to present a large amount of interesting and useful matter to the general reader, and valuable results to the practical man.

With respect to Electricity, we shall, after discussing the laws of that force as obtained either by friction or by chemical action, proceed to the consideration of Lightning Conductors; the effects of Free Electricity on the Animal and Vegetable Kingdom; the Production of Minerals, Ores, and Gems; that instructive and interesting process called Electrotyping, &c.; and allied matters which we cannot now stop to mention.

In the applications of Magnetism—the Mariner's Compass, the Action of Iron and of Iron Vessels thereon; Electro-Magnetism as a motive power; the construction of the Electric Telegraph; and those beautiful phenomena which have been brought to light by the apparatus invented by M. Ruhmkorf, will engage our attention.

We propose introducing, as an appendix to our discussion of the Undulatory Forces, a treatise on Acoustics, or the Laws of Sound. This may, at first sight, appear incongruous to those who are unaware of the analogy which exists between the four forces we have hitherto spoken of, and the effects produced by vibrations of the air. This difficulty will, however, immediately disappear, when we reflect that, as sound is certainly caused by undulations in the atmosphere, and as we can measure the lengths of these with great accuracy, it follows that sound actually becomes an explanatory key of all the phenomena which may arise from the undulations of a supposed ether. Indeed, the reader may instantly combine his *accurate* knowledge of the laws of atmospheric vibrations, with *theoretical* ideas of those produced in ether. We may, with advantage, dwell for a short time on their analogy. If a string be tightly stretched between two points, as in the violin and harp, and be made to vibrate, the sound produced is propagated by the vibration producing others in the surrounding air, just as successive waves are produced on casting a pebble into a still pond of water.

Again, if the length or tension of the string is varied, the sound produced will be proportionally altered from a bass to a treble. Transferring our attention to light, we equally assume that a vibration produces that force; and if we increase the number of these vibrations in a given space, the intensity and nature of the light produced is at once affected. The analogy between sound and light is therefore undeniable.

But we may go still farther: for if we cause a set of sonorous vibrations to cross each other, their sound either is doubled, or entirely disappears; just as two waves of water, when coming in contact, either increase in size, or are destroyed. So with light, we find the interference of rays, or fits of transmission and reflection, produce analogous effects, which, by the aid of modern research, may be measured with great accuracy

In connection with Acoustics, we propose to deal somewhat extendedly with the construction of several kinds of musical instruments, so far as they may relate to scientific laws. Some interesting applications of the Conduction of Sound will be fully noticed. The human voice, and that of animals, will also be treated on.

We have thus attempted to give a general epitome of the leading phenomena of what are called the Undulatory Forces; and we now proceed to discuss them in detail. Our arrangement will be, first, to investigate the abstract laws of each force; secondly, to point out and enter into the details of its applications; and, lastly, we shall furnish copious Tables, which will be equally valuable to the *savant*, the practical man, and the general reader.

We may be permitted to offer a word of advice to those who may use our pages without the aid of a competent instructor. Whilst we have endeavoured to be as plain and as concise as possible, still we cannot conceal the fact that difficulties will necessarily arise to those who have not had the advantage of a course of scientific training. On such we urge, that they leave no subject until they have mastered its details. If they do not pursue this course, they can only be compared to a general who, having passed through a hostile country, leaving behind him hosts of minor foes that he may press on to give battle to the powerful one, will, on his return, find that the petty enemies he had despised have combined against him, and are more to be dreaded than the apparently stronger foe. A general and superficial study of the laws of nature may give a smattering of knowledge, but can never afford solid pleasure. Of those who adopt that course, it may be safely said—

"A little learning is a dangerous thing."

Such persons are always foremost in the rank of inventors: they strike out sparks of light; but the genial benefit of sound advantage is never a product of their career.

Those, however, who will patiently and perseveringly devote a modicum of intelligence to Studying Nature, do not only derive great personal advantage, intellectually and pecuniarily, but they form a class of men on whom the world may reckon as its benefactors; and of whom it may be said, as of a Watt or of a Stephenson—.

"Si monumentum queris, circumspice."

The following is the order in which we shall proceed in treating on the Undulatory Forces:—

1st.—Heat and its Applications.
2nd.—Light ,, ,,
3rd.—Electricity ,, ,,
4th.—Magnetism ,, ,,
5th.—Acoustics ,, ,,

SECTION I.

HEAT, AND ITS APPLICATIONS.

In our Introductory Chapter we referred chiefly to those elementary facts which may be considered as the basis of Natural Philosophy. It will be necessary to recur frequently to what may be termed the axioms of science, on which we there treat; and, presuming that a general idea has been arrived at with respect to fundamental principles, we proceed to consider certain forces, by whose agency the external characteristics and form of all kinds of matter are modified.

To many, who are untutored in science, the heading of this chapter may be suggestive of difficulty. We therefore proceed to define the term "undulatory forces."

In producing motion by mere mechanical action—such, for instance, as in removing a body from its position, we are conscious of exercising a force, and such is put into operation by vital action. We will to do anything, and action may or does follow. The sequences of cause and effect are so immediate, that we do not attempt to trace their relationship.

When, however, we do not apply *directly* the vital force, but employ others, such as heat, &c., to produce a certain result, we necessarily inquire into the intermediate steps which exist between our will and the effectuation of its desire; and, in this intermission, we naturally seek to know what intervening causes have been called to our aid. Nothing is more simple than to remove a body by mere exercise of the muscles. When, however, we employ an agent, as in the propulsion of a ball from a cannon, we see that a variety of powers or forces are called into operation; and the object of science is to ascertain their nature, and to measure their extent and duration.

The most cursory observation will show that many natural occurrences owe their origin to a quasi-animate force. If, for instance, we carefully balance two weights at each end of a lever, we shall cause one to descend, or to weigh down one end of the lever, if we expand that end by the application of heat. An intelligent observer will not be content to ascertain the facts of the case: he will endeavour to find out the reason of such an effect; and to such inquiries, in reference to "Thermotics," or the Science of Heat, we now direct attention.

It has been already remarked, that a body is composed of infinitely small particles, called atoms. We do not know what the ultimate state of matter is. We believe, however, that its bulk, or the space any body occupies, is solely owing to the comparative presence or absence of heat or caloric.

The question, however, arises as to the nature of a force whose agency has so great an influence on natural phenomena; and to account for this, various theories have been advanced. It has been supposed that heat, like matter, has a solid nature; or may be made up of ultimate particles, just as matter is presumed to be. To this idea there seems to be a fatal objection. For if a body is what we may term *solid*, our experience teaches that its bulk is rarely enlarged, except by the introduction into its pores of another body, equal at least to it in solidity. Thus, we cannot divide a piece of wood by means of another piece of exactly the same nature as itself, unless we use also a force equivalent to overcoming the inertia of the particles of the body which we propose to divide.

Now, if we presume heat to be a material substance, we must, from our practical knowledge of its nature, admit, that being so subtle, it has yet escaped the evidence of our senses so far as solidity is concerned; and yet if it acts as matter in expanding a body, it must have a force which ordinary solid matter has not. Indeed, to state the case plainly, we must, assuming that heat is material, at once assert that a less solid body, by its own inherent power, has the ability to overcome the inertia of a mass possessing a resistance greater than the power which is exercised. The material theory of heat may thus be reduced to an *argumentum ad absurdum;* and to the general reader, it may be better understood, if we illustrate our position through the idea of dividing a mass of gold as the solid, by a film of air as the mechanical agent.

The material theory of heat is, however, often employed to illustrate some of the phenomena which occur during the abstraction from, or addition of caloric to a body. We often hear at the lecture table such expressions as "forcing or squeezing out heat;" and to the philosopher, no danger arises of misconception, because he uses and hears such terms as mere accommodations, whose object is to popularise ideas, and to make them accessible to those who have not had the advantage of scientific training. Astronomers take similar liberties with the facts of their science. We thus hear them speaking of the "daily motion of the sun," &c.; electricians speak of "currents of electricity," &c.: all of which are permissible, but, at the same time, have a great tendency to retard the progress of that rigid mental qualification called truthfulness, which it would seem that Experimental Philosophy has for the base of its operations.

Quitting the material theory of heat, or, as it has been sometimes called, the "corpuscular," because corpuscles, or small particles, of this quasi-material were supposed to emanate from heated bodies—we now proceed to investigate what has been termed the "undulatory theory," or that which explains the production and effects of Heat, Light, &c., on the supposition that an "*ether*," by its wave-like or undulatory motion, is their mutual cause.

The term undulatory has been derived from the Latin word *unda*, a wave; and the reader will understand the nature of the whole theory by performing what at first sight may seem a most childish experiment; but which has, in its application, as much effect on the scientific theories of the present day, as had the notable one observed by Newton—namely, the falling of an apple. The Deity impresses the same causes into His wise purposes, whether that a hair shall fall from our head, or that a world shall travel in its orbit—the most insignificant and the grandest effects alike owing their cause to the action of one universal law.

On casting a pebble into a still pond, it will be observed that the water forms a series of circles, all of which have the point where the stone first touched the water as their common centre. These waves, or undulations, thus created, continue to be produced, until the edge or bank of the pond prevents their further propagation. At first sight it would seem that the water really moved in a horizontal direction from the centre: but, on a careful examination, such will not be found to be the case. Each particle of water communicates its motion to that next to it; and thus each particle is scarcely disturbed horizontally: the action rather raises the particles in an upright or vertical position; and thus the apparent and actual motion afford a paradox, and also a refutation to the general idea, "that seeing is believing."

A very familiar illustration of the fact, that the *body* or *mass* of the water does not move, is found in the case of a swan or other bird floating on ruffled water. Instead of the bird moving in the apparent direction of the waves, in the absence of tide or current, its body will retain its *horizontal*, although its vertical or perpendicular position will undergo continual change.

By refining the ideas or imagination, and supposing the existence of an extremely rare substance, which has been called "*ether*," undulations in this material have been suggested as the cause of the forces of which we have now to speak; and, as we shall presently show, that although the idea or theory has no exact foundation, still it has the inestimable advantage of explaining a variety of phenomena for which we have no equally suitable expression.

Taking as a postulate the existence of an ether, we proceed to speak of its motion as the cause of forces; and we may here remark, that whilst the undulations of the ether may be *proximate* causes, we assume the existence of some unknown force, the action or suspension of which is the *ultimate* cause of the proximate. Of the ultimate cause we are ignorant; we can only assign its origin to the First Cause, of whom it has been recorded—

> "God said, Let there be light, and there was light."

When two pebbles are cast into the same still sheet of water, it will be found that the waves produced destroy each other when they come in contact in certain positions. Transferring our attention to the undulations of ether in a binary or twofold form, we can thus explain the cause of interference and polarisation; and assuming that any number of undulations may be produced by a similar number of initiative motions, we can, by applying the doctrine, explain a vast variety of the phenomena of the forces now under discussion. The reader will do well to study the effects produced by casting stones into still water, and by watching the results afforded when the radial waves intersect each other. Indeed, we cannot recommend any plan so effective for inducing an appreciative idea of the various laws to which the undulations of a fluid are subject.

Presuming that ether has been put into motion in one direction only, we can at once explain the phenomena of the conduction, convection, &c., of heat; for we have only to suppose motion to have been primarily imparted, and we can assume that it is propagated in every direction, and in every part of the body, from the centre to which motion had been first applied.

Thus, if a nail or match be struck, the percussion is supposed to set ether in motion or undulation: hence the production, radiation, and diffusion of heat, &c. If we presume a double or any number of motions to have been induced, we can understand that they may interfere with each other, and so produce double refraction, polarisation, and analogous phenomena.

Again, as all forces from a common centre must diminish in power, because they extend over a space equal to the square of any relative distance from the central point, so the undulation of an ether being at once a central and radial cause, will produce effects obedient to the same laws. In practice, we observe that a body giving off any amount of heat, will, at a distance of two feet, seem to afford but one-fourth of that which is perceived at one foot from it; at three feet, the intensity of its radiant heat seems to be but one-ninth, and so on. The calculation, therefore, of the forces of heat, light, &c., becomes one of mathematical precision; and the laws of circles and conic sections are of extreme value, and, in fact, a necessity, in arriving at accurate measurements of the intensities of these forces, and in arranging such in a tabular form.

Having thus shown the feasible, probable, and applicable nature of this undulatory hypothesis, we shall not further enter into the subject for the present. Under the heads of Light and Acoustics, we shall have to enlarge considerably on these remarks. Recapitulating our statements, and extending them for our present purpose, we presume—

1. That Heat, Light, &c., are produced by the undulations of an ether.
2. That these undulations may be propagated through space, and in the pores of a body.
3. That the rapidity of these undulations, which is exceedingly great, and that their regularity in one direction, or their mutual interference, are the causes of the intensity of the forces to which we have alluded, and also of their modifications.

Lastly. That the undulations of ether are caused by the application of a force which produces the motion of its parts, and consequently its phenomena.

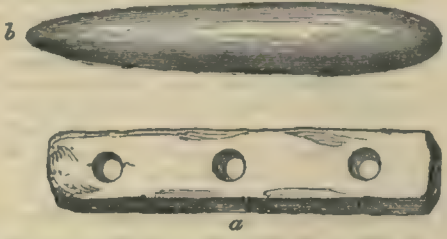
THE PRODUCTION OF HEAT.

The best known source of terrestrial heat is the sun; but the cause of its heat and light has been hitherto unascertained. By some it has been suggested that an extensive combustion is going on in that luminary. Recent observations on the solar spots, or black patches which occasionally appear on the disc, by no means countenance such views; and, indeed, it would seem that the body of the sun presents the black appearance thus observed, and that an external atmosphere has the power of either producing light and heat, or of, by some unexplained means, inducing these effects on the earth. Future researches, more especially in connexion with polarisation, may eventually lead to more correct views in respect to the cause of the forces present in the solar rays.

There is no doubt that the heat which all terrestrial bodies afford has been chiefly gathered from the sun: and thus, although generally unobserved by the senses, may be educed, by various means, to a large extent. The different processes employed for the purpose we shall now enumerate. They are chiefly Mechanical, Chemical, and Electrical.

Friction is a well-known cause of the production of heat, and, in civilised and savage nations, is equally employed for affording flame for the ignition of fuel. The common lucifer-match is well known in Europe, and has succeeded the now old-fashioned flint and steel. In Greenland, and in many tropical countries, the inhabitants produce sufficient heat, by the friction of dry wood, to ignite fuel, &c. The annexed engraving illustrates an instrument used in the arctic regions. It consists of a straight piece of dry wood (*a*), into holes in which the end of a small roller (*b*) is rapidly rubbed, in much after the same style that a hole would be bored in any solid; and thus a piece of dry moss may be easily ignited.

Fig. 1.



In the operation of boring cannon, it has been found that the friction evolves sufficient heat to boil water; and it has been stated, that a brass cannon, about seven-and-a-half inches in diameter, will, whilst the borer makes thirty revolutions in a minute, under a pressure of 10,000 pounds, produce sufficient heat to boil eighteen pounds of water in two hours and a-half.

In the Exhibition of 1851, in London, an instrument was used, which, by the friction of metal plates, afforded sufficient heat to keep various refreshments ready for use, such as coffee, &c.; and an arrangement has lately been patented, whose object is to introduce this novel mode of heating liquids into general employment.

The axles of wheeled carriages frequently become heated by their friction against their bearings. Steam and spinning machinery are often seriously injured from a like cause; and many extensive fires have been produced through neglect in oiling their different parts. The ordinary mode of grinding steel articles is an illustration of light and heat being evolved by friction; and so extended is the production of heat by such means, that two pieces of ice may be made to melt by being rapidly rubbed against each other.

Percussion is another source of caloric; and of this numerous instances are found in daily life. The cap universally employed in fire-arms, depends for its action on the sudden evolution of heat by rapid percussion, produced by the hammer falling, and compressing the fulminating mercury which the cap contains. By hammering a stout iron nail on an anvil, sufficient heat will be afforded to ignite a match; and at one period a similar plan was adopted by artisans, for the purpose of obtaining heat to light the fires of their forges. In the process of coining, the sudden percussion or compression employed, produces considerable heat. By suddenly compressing air in a suitable vessel, sufficient heat may be obtained to ignite a piece of tinder. The philosophical instrument-makers supply a syringe for the purpose of illustrating this interesting fact.

A change of bulk is generally attended with the production or loss of heat, as a natural result of the contraction or expansion of a body. Further remarks on this subject will be found under the head of Latent Heat.

Chemical Action is the source very generally resorted to, for the purpose of affording heat for social and economic purposes; and combustion, as being the most important, demands special attention. In the ordinary process of burning fuel, the natural heat contained therein is called out by intense chemical action; and just in proportion as this action is intensified, so is the amount of heat increased. The draught of a tall chimney, of the blast of the locomotive steam-jet, and of the fan or pump of the smelting-furnace, each effect the rapid promotion of chemical action between the oxygen of the air and the charcoal, &c., contained in the fuel, and so produce an intense combustion and great heat.

The production of heat by chemical action, is so often presented to the notice of the chemist, as to embarrass our attempts to make a selection. The following experiments, however, will tend to illustrate various instances of the kind:—

Experiment 1.—Mix together two parts of chlorate of potass with one part of powdered lump sugar, and drop on the mixture a little strong sulphuric acid. The chemical action which ensues will cause the rapid production of heat and light.

Experiment 2.—Dissolve some phosphorus in bi-sulphide of carbon, and pour the liquid thus obtained on some paper. In a few seconds the liquid will evaporate, and the solid phosphorus, being left in a minute state of division, will ignite, owing to the chemical action of the air; and sufficient heat will be produced to consume the paper.

Experiment 3.—Mix suddenly equal volumes of sulphuric acid and cold water. The two liquids will condense into a smaller bulk, and great heat will be evolved.

The addition of cold water to newly-made lime, affords another instance of the production of heat by chemical means. Amongst the bricklayers this plan is often used for the purpose of heating their tea. It has been patented as a method of affording heat for domestic requirements; and to so large an extent is caloric disengaged in this manner, that stables and outhouses have been destroyed by fire, owing to heavy rain-storms moistening lime which had been stored in them.

Spontaneous Combustion is often a dangerous source of heat, and is caused by the chemical action of air on oily substances, when these are in contact with fibrous matter, such as cotton and hemp. If a small piece of cotton wool is dipped into linseed oil, and then placed under gentle pressure, it will generally inflame at the ordinary temperature of spring or summer. From this cause, the destruction of cotton-waste stores and mills often takes place. This result is greatly promoted by a minute state of division, one instance of which may be found by trying the following experiment:—

Experiment 4.—Introduce some dry tartrate of lead into a narrow glass tube, having one of its ends sealed. Heat the tube until no more acid vapours pass off, and then instantly seal the open end. If the tube is broken, when quite cold, the fine particles of the lead will inflame on coming into contact with the air, chemical action being the cause of the heat thus produced.

The most intense heat which can be produced by chemical means, is that afforded by the combustion of a mixture of coal gas or pure hydrogen, and oxygen gases. This is generally effected by means of a peculiar form of blow-pipe, so arranged as to prevent risk of explosion. As this will be fully described in the chemical section, we shall not further allude to it here than by stating, that by these means the most refractory metals may be melted, and the earths fused: there are few solid substances which cannot by its agency be reduced to a fluid state, or be dissipated in vapour.

Electricity is another source of heat, to which special attention will be called in the proper place. By means of electricity, produced by chemical action, the most powerful effects of heat are afforded.

Vital Action is a source of heat with which all are familiar; and it seems chiefly to depend on the slow combustion which the food undergoes, after being absorbed by the stomach, and conveyed to the surface of the lungs, in the form of highly carbonaceous blood. The charcoal contained in the blood undergoes combustion by coming in contact with the inspired air; and in every respect the process is analogous to that which is observed in the burning of coals in the ordinary fire-place.

The intelligent reader will not fail to remark, that in every source of heat which has been enumerated, motion has been the leading cause; and a general statement may be made, that whenever motion is produced in matter, heat is simultaneously evolved. It is true that daily experience does not tend to confirm such a proposition; but that is solely because the senses, and our means of measuring heat thus evolved, are far too gross to permit its detection. Heat, Light, Electricity, and Magnetism are mutually producible: all matter seems to contain these forces; and motion, at any time, is sufficient to bring them from a latent to a sensible state.

THE EFFECTS OF HEAT.—EXPANSION.

Having spoken of the various sources of heat, we must next enquire as to its effects on matter generally; and it is necessary to bear in mind, that any results to which we shall allude, are produced, not *in* the atoms of which a body is composed, but rather *around* them, modifying and changing their relative positions. Many errors are often fallen into with respect to this point; and nothing is more injurious to true progress in scientific study, than a careless appreciation of the lessons and laws which it teaches.

There are but three states in which a body is found: the solid, the liquid, and the gaseous or as vapour; and, as it has already been observed, these states are modifications of each other, effected by the presence or comparative absence of heat. According to the generally received doctrine, it is assumed that a solid is so, because its particles are near to each other, or in close approximation—that a liquid is produced from a solid by the addition of heat, which has the effect of removing the particles of a mass from each other; and that by still further carrying on the process, a gas or vapour is formed, wherein the separation of particles is still more effected.

It would thus be seen that heat has what is called a repulsive power: in other words, it can lessen the cohesion of particles, and so enlarge the bulk they occupy in mass. As we shall presently find, the addition of heat almost always increases the size of a mass; and hence has arisen the idea that it repels the constituent particles of that mass. When, however, a body has changed its state by this expansion, other laws govern its further increase in bulk. Indeed, there is a special law of expansion incident to solids, liquids, and gases; and these considerations are of the utmost importance in physical science and its applications.

The expansion of solid bodies varies considerably on their receiving an equal addition of sensible heat; and they expand in all directions, although differing in individual extent. A very simple way of showing the expansion of a metal, both in respect to its length and breadth, may be thus tried:—

Experiment 5.—Fit a brass ring very accurately on an iron rod; having removed the ring, heat the rod nearly to a red-heat, and attempt to replace the ring. It will be found, that owing to the expansion of the metal, the ring cannot be passed on to the rod until the latter has cooled down.

Experiment 6.—Fix an iron rod, whilst cold, so as that it may exactly rest between two points touching each of its ends. On heating the rod, and attempting to replace it, its expansion lengthways will be found to prevent its resting between the two points, because they will be at less distance from each other than are the two ends of the heated metal. The rod, on cooling, will again fit between them, owing to the loss of heat and subsequent contraction which it undergoes.

Having thus illustrated the linear and general expansion of a solid by the agency of heat, we remark that different bodies expand at unequal rates; and perhaps the simplest illustration of this is afforded by the following experiment:—

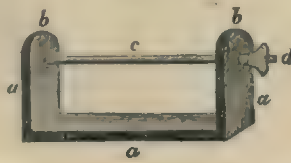
Experiment 7.—A piece of brass bar, an eighth of an inch thick, one inch wide, and eighteen inches long, is to be firmly rivetted to an iron one of the same size, care being taken that the two shall form a straight bar when completed. On heating such an arrangement, it will immediately take a curved form, because the metals expand unequally. The brass, expanding more than the iron, will form an arch, enclosing the iron. The bar will regain its straight form on again becoming cool.

A vast variety of interesting applications of this law of expansion by heat are made in daily life. The tires of railway wheels are made to embrace the spokes tightly, by making them a little too small when cold. On heating the tire, it expands, and can then be passed on to the ring of metal in which the spokes end. On cooling, the tire contracts with great force, and so remains completely fixed in its desired position. The tires of carriages and cart-wheels are affixed in a similar manner; and some parts of machinery are thus easily made to retain their position, such as in the case of rings or pulley-wheels, often secured on shafting. In constructing railway and other iron bridges, allowance is always made for expansion by heat; and in laying down the rails on the track of a railroad, sufficient space is left between each metal to permit free extension. On a railway where sufficient allowance had not been made, the rails were lifted, during a hot summer day, several inches from the ground. The rails on a line of railway of two hundred miles' nominal length, will be some hundred feet longer in summer than in winter time, presuming the absolute length of iron surface is carefully measured.

It has been noticed that a rod of metal will contract to its previous bulk, when the heat which had caused its expansion had been lost. An interesting experiment may be adduced in illustration of this fact.

Experiment 8.—In an arm of cast-iron *(a)*, represented in Fig. 2, have two holes made at *b*, so that a rod of wrought-iron *(c)* may be screwed tightly, by means of a thumbscrew, as at *d*. Remove this rod, and heat it red-hot, afterwards replacing it in this state, and screwing it firmly in the arms of the cast-iron frame. On pouring cold water on the hot iron, the metal will rapidly contract, and in so doing, will act so powerfully on the cast-iron frame as to break it into pieces, with a loud report.

Fig. 2.



An adaptation of this experiment has been occasionally employed for the purpose of restoring walls which had bulged outwards. Iron plates are fixed on the outsides of the wall, and a stout iron rod is stretched between them, and firmly screwed at its extreme ends, beyond the plates. On the rod being heated, it of course expands, and is again screwed up tight. On contracting, it draws together the plates and walls with great force. A repetition of the process generally succeeds in restoring the perpendicularity of the walls of a building, and is easy of application.

Serious accidents have happened in cases when builders, on fastening iron girders resting between stone walls, had neglected to make allowance for the expansion of the metal. In many instances, extensive erections have been thrown down: for as the iron expands in length, it forces the walls outwards; and should no immediate apparent mischief result, still the alternate expansion and contraction has the tendency of weakening the brickwork, and thus of endangering the stability of the building.

The annexed table, which has been arranged from various sources, gives the linear expansion of the substances named, on their being raised from a temperature of 32° F. to 212°; and is to be understood as expressing the ratio of their individual expansion, in the order in which that increases.

Glass Tube	0.000861
Platina	0.000884
,,	0.000992
Iron	0.001220
Gold	0.001466
,,	0.001555
Copper	0.001722
Silver	0.001909
Lead	0.002848
Zinc	0.003011

The above numbers are expressed in decimals, as giving a greater amount of accuracy than would have been arrived at by employing vulgar fractions; and the standard is unity. Hence the length of a bar of metal will be increased to the extent of its original length, multiplied by the factor in the table, on the temperature of the metal being raised the number of degrees above indicated.

Various interesting applications of the law of the expansions of solids will be mentioned in the section on Mechanical Philosophy: such as the regulation of pendula, watch-springs, and other similar matters. Their introduction in this place would tend to distract attention from the laws to which we prefer for the present to confine our remarks.

Expansion of Liquids.—As a general rule, liquids expand far more in bulk, by the same increase of temperature, than solids; and hence these changes become more evident to the senses. They have been chosen as the fittest media for the purpose of measuring the temperature of bodies within a limited range. Hence the construction of thermometers of various kinds, to which we shall now devote our consideration.

That liquids expand considerably on being heated, is often observed in daily life. If a kettle, completely filled with cold water, is heated, the liquid it contains gradually expands, and soon passes out of the vessel. A more philosophical mode of illustrating this effect, is that of fixing into a glass flask a long, narrow glass tube, and filling the vessel with coloured water, so that a portion of the liquid shall also rest in the tube. On heating the flask, the water will gradually expand, and will do so according to certain laws, indicating its expansion by rising in the tube until the boiling point is reached. On this principle the thermometer is constructed; mercury, however, being generally employed in preference to other liquids, except for special purposes.

Liquids, like solids, vary much in their relative expansion on receiving equal increments of heat; and without giving a tabular form of these, which could not be done with accuracy, we may state that mercury expands least, and alcohol (pure spirits of wine) expands most, on being exposed to the same increase of temperature. The total expansion of a solid by heat is very nearly ascertained by multiplying its linear extension by three. In the case of liquids, they naturally accommodate themselves to the shape of the vessel which contains them, and as a solid that will expand also. It is therefore necessary, in every instance, to make an allowance for this in constructing instruments for measuring changes of temperature by means of liquids. There is in every case, with but one exception, a constant contraction sustained by liquids on their losing heat; and thus they afford means of ascertaining temperatures which may be much below those experienced in daily life.

This exception is that of water; and in it we find a remarkable instance of an apparent suspension of a universal law for effecting a special end. At a temperature of 40°, water ceases to contract; and as it approaches a temperature of 32°, its freezing point, it expands considerably; so much so, indeed, that if confined in a closed vessel of great strength, it will, on freezing, expand sufficiently to rend the vessel into fragments. This singular exception has an astonishing effect in influencing the climate of the polar regions. If water contracted continuously on suffering a decrease of temperature, it would, on arriving at the solid state of ice, at once sink to the bottom of a vessel from its attaining an increased specific gravity; but through the expansion which takes place as it cools, this cannot occur. Hence we find the ice on the *surface* of the rivers and the sea, ready to receive the rays of solar heat, which will again change it to the liquid state—a result which could never occur if, obeying the usual laws, it sank, when formed, to the bottom of the ocean. This circumstance may be adduced as one of the most striking proofs of the existence of an OMNISCIENT BEING.

The ordinary thermometer consists of a glass tube, of small diameter, one of whose ends has been blown into a bulb. This and a portion of the stem is filled either with mercury, or spirits of wine which has been coloured; and after expanding the fluid until it completely fills the stem, the open end is hermetically sealed or closed. A scale is then made, whose object is to ascertain comparative temperatures. Various scales are employed; such as those of Reaumur, the Centigrade, and that of Fahrenheit. Confining our attention to the latter for the present, we shall describe the mode adopted for making the scale which is invariably used in this country.

On the bulb and stem being completed, the former is dipped into a vessel containing melting snow or ice; and when the mercury in the stem ceases to fall, a mark is made on the glass. This indicates the freezing point of water, which is denominated by Fahrenheit as 32°. Water is then heated in a *metal* vessel (one of glass, &c., will not do); and when the water, which should be quite pure, boils, another mark is made at the point to which the mercury has risen in the stem. The interval between the freezing and the boiling point is divided into 180 equal parts, or degrees. Hence, on the scale we here refer to, water boils at a temperature of 212°.

We shall not enter, at present, into various corrections which must be made for the expansion of the glass bulb and tube, each of which has the tendency of inducing errors in observation; as these points will be fully considered under the head of Meteorology. Spirits of wine is usually employed for measuring very low temperatures, as it is not liable to freeze—an occurrence which would happen to mercury, even in the temperature of the arctic regions, at some periods of the year. The scale of Reaumur has but 80° between the freezing and boiling points of water; and as this is often used in foreign scientific works, we append a rule for converting the degrees of each scale to that of the other.

1. To convert the degrees of Fahrenheit's scale to those of Reaumur, multiply the number of degrees of Fahrenheit, from which has been subtracted 32, by 4; and divide the amount by 9: the quotient will be the degrees indicated by Reaumur's scale.

Example.—What number of degrees will be shown on the scale of Reaumur, if the temperature indicated by that of Fahrenheit is 212°?

Subtracting 32 from 212, leaves 180.
Multiplying 180 by 4, gives 720; and,
Dividing 720 by 9, ,, 80°.—*Ans.* 80°.

2. To convert the degrees on Reaumur's scale to those of Fahrenheit, multiply those of Reaumur by 9, and divide by 4; to the quotient add 32, which will give the number sought.

Example.—What number of degrees on Fahrenheit's scale corresponds with 80 degrees on that of Reaumur?

Multiplying 80 by 9, gives 720.
Dividing 720 by 4, ,, 180.
Adding 32 to 180, ,, 212°—*Ans.* 212°.

The above calculations evidently rest on the fact, that nine of the degrees of Fahrenheit's scale are equivalent to four degrees of that of Reaumur.

The Centigrade scale is divided into 100° between the freezing and boiling points. Hence, five degrees on this scale correspond with nine degrees of those on Fahrenheit's scale.

3. To convert the degrees of Fahrenheit to those of the Centigrade, multiply the number of the former, less 32, by 5; and divide by 9: the quotient will afford the corresponding degrees of the Centigrade scale.

Example.—What is the number of degrees on the Centigrade corresponding to 212° Fahrenheit?

212 less 32, equals 180.
180 multiplied by 5, gives 900.
900 divided by 9, equals 100°.—*Ans.* 100°.

4. To convert the Centigrade to the Fahrenheit scale, multiply the former by 9; and, dividing by 5, add 32 to the quotient.

Example.—What number, on the scale of Fahrenheit, corresponds with 100° on the Centigrade scale?

Multiplying 100 by 9, produces 900.
Dividing 900 by 5, ,, 180.
Adding 32 to 180, gives 212°.—*Ans.* 212°.

The following skeleton table may be of assistance in many instances, and, occasionally, will save the trouble of calculation:—

Comparative indications of thermometers of the scale of—

	Fahrenheit.	Reaumur.	Centigrade.
Freezing point . .	32°	0°	0°
Boiling ,, . .	212°	80°	100°.

Various forms of instruments for measuring heat will be fully noticed in other parts of the work, as coming more especially under other subjects: among these we include the air, registering, and dew-point thermometers; as also Breguet's, and an interesting instrument, by means of which electricity is employed for ascertaining minute changes of temperature. We have omitted to give exact directions for constructing a thermometer, because long practice is necessary to produce even a tolerable instrument; and the cost of such is very slight, if purchased of the instrument-maker.

Having thus described the thermometer as an instrument which enables us, by the expansion of a fluid, to ascertain the comparative temperature of bodies, we proceed to notice some of those natural and ordinary effects which depend on the expansion of liquids by heat for their proximate cause.

In every instance in which a liquid is heated, it becomes lighter than that of a lower temperature; hence it has a tendency to ascend. This effect is magnificently illustrated in the case of the gulf stream, which sets in towards our western shores from the Gulf of Mexico. Its temperature is much higher than the surrounding ocean, and it accordingly floats on the surface of a colder, and therefore denser, fluid. In domestic life this law is taken advantage of; hence the construction of hot-water apparatus, in which the hot water rises through an upper pipe, and, when cooled, returns by one placed at a lower level. The character of these currents of heated liquid, and their tendency to rise, may easily be noticed by trying the following experiment:—

Experiment 9.—Throw a small piece of litmus, or indigo, into a glass flask nearly filled with cold water, and placing the bottom of the flask over the flame of a candle or lamp, it will be noticed, that as the lower stratum of liquid becomes heated, the colouring matter will rise with it; and, on the liquid cooling, it will return to the bottom of the flask, again to undergo a similar process.

EXPANSION OF GASES.—Gaseous bodies, such as air, expand still more than liquids, on the addition of heat; and the cause and applications of this fact, form a most interesting feature in Physical and Natural Science, the results being more definite and constant than those found in the expansion of solids and liquids.

The simplest mode of illustrating the fact, that a gas, such as air, expands by an addition of sensible heat, is by plunging the stem of a retort or thermometer tube, full of air, beneath the surface of water, and applying heat to the bulb. On the air expanding, a portion will escape in bubbles through the water; and on the source of heat being removed, the water will rise in the neck, to take the place of the air which has been expelled by heat.

Air thermometers are constructed on this principle; and a very simple one may be made by fixing a glass tube, by means of a cork, into the neck of a glass flask. If the flask is partly filled with a coloured liquid, and inverted so that the end of the tube shall rest in a cistern of water, the air remaining in the flask will expand on a slight increase of its temperature, and the liquid in the tube will be driven downwards, recovering its position on the application of heat ceasing. Differential thermometers are of this kind, but have two bulbs, into one of which the liquid passes on the expanded air pressing it downwards.

Nearly all gases expand equally on receiving an equal increase of temperature; at least, in practice, their differences may be neglected for all ordinary purposes. After careful experiments, it has been ascertained that they increase in the proportion of $\frac{1}{493}$rd part for every degree of temperature rising from the freezing point of water, or 32° Fahrenheit.

In other words, if a volume of air measure 493 parts at 32°, it would become expanded to 986 parts on attaining a temperature of 525°. Any intermediate result may be obtained for other temperatures by adding $\frac{1}{493}$rd part for each degree of increase. The following formula expresses this rule, where x represents the volume sought, a the normal volume, and t the number of degrees of increment of temperature; 32° Fahrenheit being the standard :—

$$x = a + \frac{a}{493} t$$

To illustrate this we will suppose that it is desired to ascertain the expansion which air will undergo by being heated from 32° to 212°. Supposing a is taken as 100 parts, t as 180°, being the difference between 32° and 212°, we shall have

$$x = 100 + \frac{100}{493} \times 180^\circ = 136.5$$

or, one hundred parts of air, on being heated from freezing to boiling point, expand to one hundred and thirty-six parts and a-half.

In applying this rule to other gases, an allowance has to be made for very slight variations in the ratios of expansion. We have, in our example, supposed that 100 parts of air expands to a volume of 136½, on being heated from 32° to 212° Fahrenheit. In the following table, the ratio of the different expansion is stated for a similar change of temperature in various gases, unity being the standard, and on the authority of Regnault :—

Air	1.36700
Hydrogen	1.36613
Carbonic acid . . .	1.37099

By multiplying any number of volumes by the above factors, the actual expansion which they will undergo by being heated from 32° to 212° is at once obtained.

Having thus explained the laws which govern the expansion of aëriform or gaseous bodies, we may pass on to consider some instances in which their application becomes a matter of general interest.

The various changes of the wind depend on the unequal expansion of the atmosphere by the agency of heat. Expanded air being lighter, of course tends to rise, and, consequently, air of a more dense and cooler nature rushes in on all sides to take its place. We thus have either the gentle breeze, the hurricane, or the whirlwind. To the engineer, the expansion of gases and vapours is of the utmost importance; and, within the last few years, heated air has been extensively employed as a source of motive power by Ericson and others; of which we shall speak under the head of Mechanics. In daily life we have to study and apply the laws of expansion in attempting the ventilation of public and private buildings —a subject to which we shall draw special attention hereafter. It would be impossible to enumerate all the instances wherein these laws exercise an influence. We, however, cannot fail to remark, that an astonishing range of application exists in the effects of expansion by heat; for, under the same cause, the fierce storm in one place may be spreading desolation, whilst the gentle current of air is supporting existence, in its quiet obedience thereto in other situations. We thus observe how one cause may be productive of a multiplicity of effects; and, perhaps, one of the greatest charms of experimental science, is the frequent disclosure of such interesting instances of design and adaptation of means to an end, which the attentive student is continually witnessing.

THE EFFECTS OF HEAT.—LIQUEFACTION AND FUSION.

We proceed to consider the effects of increasing the temperature of bodies by the addition of sensible heat; and we shall find that unequal results are produced on equal increments of heat being made to various substances. We have already noticed, that whilst some bodies are generally found in a solid state, others take that of the liquid, or gaseous, at ordinary temperatures; and the most cursory observation will show, that an addition or abstraction of heat would be necessary to render all bodies of a uniform condition.

The terms "liquefaction" and "fusion," although they appear at first sight almost synonymous, have, nevertheless, very different significations. We liquefy, or render liquid, ice; but, generally speaking, the term "fusion" is applied to the process of melting solids, such as lead or rock-crystal; and although ice is as much a solid as glass, still there is considerable convenience in maintaining this distinction of terms.

On increasing the sensible temperature of a substance, the effects vary considerably. On heating ice, the solid is immediately converted into a liquid; and the most accurate observations fail to trace any notable effect intervening between these two conditions. If, however, zinc is submitted to the same process, we find that its solid state is considerably modified; and, whilst brittle at first, it becomes softer and more malleable before it enters into a state of fusion. The metal tin becomes pulverisable, or, rather, easily divisible at high temperatures; and masses of iron or platina may be welded or united together at a heat below their point of fusion.

It will be thus observed, that a variety of phenomena may occur between the solid state and its conversion into that of a liquid. The separate causes which induce this chain of variation are entirely hidden from us; but we presume that the series of effects results from a peculiar arrangement of the molecules or particles of which a body is composed, and is thus owing to the relative position which they may assume whilst undergoing the process of heating.

In the conversion of the solid into the liquid state, bodies of different kinds absorb unequal amounts of caloric; and, consequently, we find that their melting points vary accordingly; or, which is the same thing, the liquid state becomes converted to the solid at different temperatures.

We shall have to consider the cause of these variations more fully when we treat on Specific and Latent Heat; but the following table will give an idea of the great difference which exists amongst solid bodies when changing their condition to that of the liquid state :—

The Melting or Fusing point, according to the scale of Fahrenheit, of—

Mercury, is	—40
Water (ice)	+32
Tallow	98
Phosphorus	110
Stearine (variable) . . .	120
Sulphur	226

It must not, however, be assumed that the solid state of bodies can be directly attained by liquids on their arriving at a temperature such as we have indicated in the foregoing skeleton table, although such is true with respect to the conversion of solids to the liquid state. The various forces of nature act together; and thus water may be cooled much below its point of congelation without becoming solid, provided it is kept perfectly still. This interference of apparently heterogeneous and yet correlative forces, may be easily observed on trying the following experiment :—

Experiment 10.—Dissolve, in boiling water, as much sulphate of soda (Glauber's salts) as the liquid will take up. This is best performed in a glass flask. Place the vessel and contents on several folds of flannel in a still place, and allow all to attain the temperature of the atmosphere, and the liquid state will be maintained. If, however, a small piece of any angular substance is dropped into the flask, or if its contents are violently shaken, the liquid will instantly pass into the solid state.

By exposing a glass vessel filled with water to a temperature below freezing point, the water will retain its liquid state for some time; but, on the least agitation, it will be converted into ice. It has been stated, that even the rays of the light of the moon will produce the same effect. We are not in a position to verify this by personal experience, and would suggest, that as there is great difficulty in maintaining a quiescent position, owing to the chances of motion being unwittingly communicated to a liquid, it is highly possible that an experiment of this kind may be vitiated by accidental circumstances.

Whilst speaking of substances which change their physical condition at comparatively low temperatures, we may mention that different bodies assume a variety of forms by the peculiar arrangement of their particles during the act of solidification. Thus we have crystals of snow, the arborescence of ice, and the crystallographic forms peculiar to each body produced at that moment. We shall devote a special article to this subject; and content ourselves, for the present, by merely mentioning the occurrences as commonly taking place.

When a solid assumes a liquid state at a temperature higher than that of the boiling point of mercury, we are obliged to resort to other means of ascertaining the temperature than the employment of the mercurial thermometer, because a temperature of 670° Fahrenheit would destroy the instrument. For such purposes *pyrometers* are employed; and although much ingenuity has been directed to construct an instrument of this class, on whose indications reliance may be placed, it is to be regretted that no great success has attended such efforts. The earliest form of pyrometer, or fire-measurer, was that of Mr. Wedgwood. It was constructed on the assumption that a piece of clay would contract in proportion to the amount of heat to which it was subjected. The student may be here surprised to learn that a body *contracts* by the application of heat; but the difficulty is only an apparent one; for when clay contracts on being heated, the effect is produced solely by the water between its particles being expelled; hence it forms no exception to the general law of expansion by heat. Owing to the variety of the texture of clay, Mr. Wedgwood's pyrometer affords unreliable results, and has, therefore, been discarded.

The late Dr. Daniell invented an ingenious arrangement, wherein the expansion of a bar of platina was made to register high temperatures. The bar is enclosed in a cylinder of black-lead crucible ware; and a piece of porcelain, which fits tightly into the cylinder, and touches one end of the platina bar, indicates, by the removal from its first position, the extent of expansion which the platina has undergone during the application of heat. By a mechanical arrangement, the expansion is registered in degrees corresponding with the scale of Fahrenheit.

Other arrangements have been made, intended to facilitate the registration of high temperatures; but, in every case, the great difficulty which has to be contended with is, that the intense heat to which the indicating substance has to be exposed, almost always vitiates the result obtained.

As it is usual, in scientific works, to give a table of the melting point of various solids, we follow that course: however, the reader must bear in mind, that some of the figures in the following table have been calculated only approximately, and are liable to the sources of error which have been pointed out.

Melting point, according to the degrees of the scale of Fahrenheit, of the metals.

Potassium	136° F.
Sodium	194
Tin	442
Bismuth	476
Lead	594
Zinc	700
Brass	1869
Silver	1280
Copper	2548
Gold	2590
Cast-Iron	3479

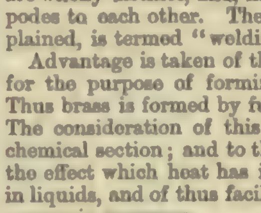
The above may be fused by means of furnaces of various kinds; but platina, and many other bodies, require the powerful heat of the oxyhydrogen blow-pipe, or of the voltaic battery, to reduce them to the liquid state.

Platina and wrought-iron, however, seem to enter into a partial fluid state long below their melting point; and hence separate masses of either of these metals may be united at a white heat, so as to form one piece. It is impossible to state definitively the reason of this property being confined to two substances; and it is the more remarkable because their physical and chemical character are wholly distinct, and, in many instances, the very antipodes to each other. The process, as we previously explained, is termed "welding."

Advantage is taken of the power of heat to fuse bodies, for the purpose of forming what are termed "alloys." Thus brass is formed by fusing together copper and zinc. The consideration of this will be duly observed in our chemical section; and to that we must also defer noticing the effect which heat has in rendering substances soluble in liquids, and of thus facilitating numerous scientific and economic processes.

A most singular effect is observed when fusion is effected by heat produced by electricity. The combination of these two forces produces the anomalous result of sometimes fusing a body so suddenly, and of permitting its reconsolidation, as not to allow time for the heat to pass to surrounding bodies; and hence, during violent thunder-storms, instances have occurred in which metallic articles, such as coins, chains, &c., worn by a person who has been struck, have been completely melted; whilst the linen or cotton on which such have rested has been entirely uninjured. We have frequently noticed that a powerful Leyden discharge will superficially melt a wire, and yet leave a piece of paper, on which the metal rested, perfectly unburnt. No adequate reason has been as yet assigned for such occurrences.

Fig. 3.



Having mentioned the leading methods of measuring intense heat by means of the expansion of solids, we must not omit to describe a very ingenious instrument, invented by M. Breguet, of Paris, for ascertaining minute changes of temperature. It is constructed on the principle that two metals, expanding unequally on receiving increments of heat, will assume a curved form—a fact which we illustrated by Experiment 7.*

The annexed engraving illustrates one of these interesting arrangements. The spiral is formed of a ribbon of silver platina and gold, soldered together. Its upper end is fixed to a stand; and to the lower one an index is attached, which, by traversing over a graduated plate, indicates a change of temperature, owing to the unequal expansion of the metal forming the spiral. This is one of the most elegant adaptations of a scientific law which has yet been made; and for ascertaining minute changes between low rates of temperature, it is a valuable instrument in the hands of the philosopher.

---

* *Ante*, p. 16.

It is scarcely necessary to point out instances in which liquefaction and fusion operate to our advantage in daily life. The processes of metallurgy, such as smelting and refining, casting, moulding, and other such operations, are sufficiently familiar. We may remark, however, that the difference of temperature at which bodies cease to be solids is a matter of great importance, and leaves an extensive choice of material for various purposes, extending from the refracting crucible used by the chemist, to the more easily melted, and therefore more tractable, substances employed for economic processes.

THE EFFECTS OF HEAT.—EVAPORATION, VAPORISATION, Etc.

Continuing to restrict our remarks to the effect of *sensible* heat, we now examine the processes of Vaporisation and Evaporation. At first sight, these terms seem convertible; but in scientific phraseology they hold a distinct meaning. Vaporisation is that process in which anything is converted into a state of vapour, by the addition of a considerable amount of heat; whilst the term "evaporation" refers to a process continually and imperceptibly going on at or about the ordinary temperature of the atmosphere. Thus steam is produced by vaporisation, and clouds, &c., by evaporation.

It will be here necessary to point out the distinction which is maintained between the terms "vapour" and "gas." By vapour we understand an unstable condition in which a body exists, so long as a comparatively high temperature is maintained. Thus the steam of water, alcohol, ether, &c., fall under this category. The air, coal gas, &c., are, however, under all ordinary circumstances, in a constant state; and hence are ranked under the term "gas." It is true that some gases, as carbonic acid gas, or fixed air, may, by great pressure and intense cold, be reduced to the solid state; but these results being extraordinary, are not considered to militate against the justice of the rule which we have laid down. We may add, that vapours can easily be converted into liquids; whilst gases present great resistance to that process; hence the distinction of the terms. The consideration of a permanent gaseous state, we shall take up under the head of Latent Heat.

The process of evaporation is continually going on at the ordinary temperatures. By placing an inverted glass over grass during the heat of a summer day, it will be found that moisture soon forms at the top of the vessel. The insensible perspiration which continually exudes from the skin of animals, the gradual loss of fluid from an uncovered vessel, and other similar instances, are due to this constant process.

Whenever evaporation takes place, cold is at once produced; and hence, if a porous vessel, containing a liquid, is placed in any position where a draught of air can act on it, the result is that its sensible temperature is much diminished. The cause of these phenomena will be more fully dealt with presently.

On applying heat to liquids, and some solids, they may be made to assume a vaporous form; but, as in the conversion of a solid to the liquid state, different liquids require unequal increments of heat to effect this purpose. Ether, for instance, is converted into vapour at a temperature of 96° Fahrenheit; whilst mercury requires that of 660° Fahrenheit: both of these, however, may evaporate at lower temperatures. The temperature of ebullition, or rapid conversion into vapour, is termed the *boiling point.*

We here refer to vaporisation as taking place under ordinary circumstances; but the boiling point of liquids varies when the pressure of the air is raised or lowered. We shall take these different cases in the order of—common pressures, the vacuum of the air-pump, and extraordinary pressure, as in the high-pressure steam-boiler.

The boiling point of liquids can easily be ascertained by immersing a mercurial thermometer in them; but a metal vessel must be employed to hold them, because those of glass or porcelain have the effect of raising the apparent boiling point, perhaps through the inferior conducting power of their material, and from other causes.

Annexed is a skeleton table, which affords the boiling point of some liquids; and it is supposed that the temperature has been taken whilst the barometer stands at 30 inches.

Boiling point, on Fahrenheit's scale, of—

Sulphuric ether	96 to 98°
Pure alcohol (spirits of wine)	173
,, Water	212
,, Nitric acid	242
,, Sulphuric acid	550
,, Sulphur	560
,, Mercury	660

If liquids are heated under a lower pressure than that of the atmosphere, they will boil at a much lower temperature, as the following simple experiment will illustrate:—

Experiment 11.—Boil some water in a glass flask, and, when in full ebullition, fit a cork air-tight into the neck of the vessel. Remove the latter from the source of heat, and dip it into cold water. Because a vacuum is thus formed, and the pressure of the air removed, the water will recommence to boil.

If ether, spirits of wine, or water heated to 98°, is placed under the receiver of an air-pump, and the air is exhausted, each may be made to boil at ordinary temperatures, because the pressure of the atmosphere, of course, cannot affect them in a vacuum. This circumstance has been taken advantage of by sugar-refiners and pharmaceutists, who are in the habit of boiling their liquids in vacuo at a low temperature, and thereby prevent the formation of certain products, which might prove injurious to their processes: economy, also, is found to accrue thereby.

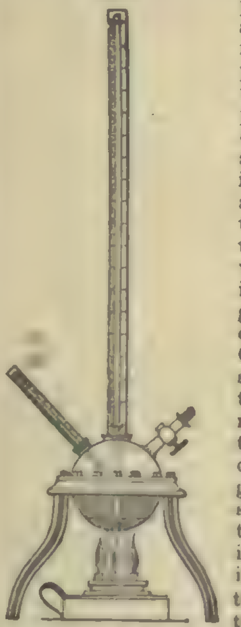
The property of liquids boiling at lower temperatures when the superincumbent pressure of the air has been removed, has been used as a means of ascertaining the heights of mountains. As we ascend in the atmosphere, the pressure decreases; the mercury in the barometer descends; and, therefore, water will boil at a lower temperature. An approximate ratio of the decrease of the boiling point, may be taken as one degree of Fahrenheit's scale to an elevation of 520 feet above the level of the sea; hence, on the top of a mountain 10,000 feet high, water would boil at a temperature of 192° Fahrenheit. Heights found in this manner are, after all, only rough calculations, inasmuch as that barometric changes may not be synchronous between the base and summit of the mountain.

The following table gives the three elements to which we have alluded—namely, the boiling point of water, the barometric height, and the corresponding elevation, in round numbers, above the surface of the earth. The barometer is presumed to stand at 30 inches at the level of the sea:—

Boiling Point of Water.	Elevation of Observer.	Height of Barometer.
212	surface	30
210	1050 feet	29
208.5	1850 ,,	28
206.5	2900 ,,	27
205 nearly	3700 ,,	26

Having occasionally employed the term "atmospheric pressure," it is necessary that we should define its meaning before proceeding further. At the level of the sea the air presses on every surface with a force of nearly fifteen pounds on a square inch. It is true that this pressure is not felt, because it acts on each and every side; and thus, on holding out the hand, we sustain as much pressure *upwards* on its under surface, as we do *downwards* on its upper side. But, if either pressure be removed, the other would at once become evident, and its existence be perceived. In dealing with pressures beyond fifteen pounds on the square inch, such are reckoned by "atmospheres;" that is, supposing air was forced into a vessel until it exercised a pressure on its sides equal to thirty pounds per square inch, such would be called a pressure of two atmospheres; if of forty-five pounds, it would be three atmospheres; and so on. This short explanation will suffice to render the succeeding remarks intelligible.

Fig. 4.



Whilst water boils at ordinary pressures at a temperature of 212°, and at about 90° in a vacuum, it is found that a much higher temperature is required to produce the same result under a pressure exceeding that of the atmosphere. An arrangement, represented in Fig. 4, is employed for the purpose of ascertaining the successive boiling points of water under such circumstances. It consists of a strong copper boiler, in which is fixed a tall glass tube, open at both ends. The bottom of the boiler contains mercury, and the vessel is half filled with water. On one side a stop-cock is fitted, and on the other a good thermometer, whose bulb enters into the metal vessel. On heat being applied, and the steam produced being allowed to escape, the thermometer will not indicate a higher temperature than 212°, and the mercury will not rise within the tall glass tube. But, on closing the stop-cock, and thus preventing the escape of the steam, the internal pressure will gradually increase, the mercury indicating this by rising in the central tube. As the mercury rises, the temperature indicated by the thermometer will also rise; showing that by an increase of pressure the boiling point is raised.

If the stop-cock is opened, the steam will escape, and the pressure will be simultaneously diminished. The mercury in the thermometer will fall to 212°, and there remain, so long as free access is allowed between the external air and the boiling water.

The following table exhibits the results obtained by an experiment of this kind :—

Pressure per Square Inch.	Height of Mercury in a Barometer Tube.	Temperature.
15 pounds	30 inches	212°
30 ,,	60 ,,	250
45 ,,	90 ,,	275
60 ,,	120 ,,	294
75 ,,	150 ,,	310
90 ,,	180 ,,	323

It will thus be observed, that the boiling point of water is increased in by no means a regular ratio under an increased pressure of vapour on its surface. Tables indicating this result have been extended to a much higher degree than that which we have presented; but the principle will be understood from what we have stated.

Liquids, on being converted into vapour, undergo great expansion. Water, when changing its liquid to the vaporous state, is expanded to about 1,700 times its previous volume. The annexed table gives the relative bulk of a cubic inch, in the liquid state, to that of the condition of vapour, of water, alcohol, and ether.

	Bulk at 60° F.	Temperature.	Bulk of Vapour at Boiling Point.
Water . .	1 cubic inch	212° F.	1690 cubic inches
Alcohol .	1 ,,	173	494 ,,
Ether . .	1 ,,	96	213 ,,

In round numbers, it is estimated that one cubic inch of water is converted into one cubic foot of steam, by being raised to the boiling point.

As the state of vapour depends essentially on the maintenance of a high temperature, it follows that, on the abstraction of heat, such vapours regain their liquid state, and, in so doing, contract from their extended to a diminished bulk. Thus steam, of a temperature indicated by the thermometer of 212°, becomes reduced to $\frac{1}{1700}$th of its bulk on returning to the condition of a liquid. The following experiment may tend to impress the fact on the mind of the student :—

Experiment 12.—In an air-tight tin vessel, having an open stop-cock, boil water until the vessel is filled with steam. A cylinder twelve inches high and three inches in diameter, made of thin metal, answers well for this purpose. When the vessel is filled with steam by the ebullition of the water, close the stop-cock, and immerse the arrangement in cold water. The steam will at once condense and return to its diminished bulk of water. The atmospheric pressure, acting on all sides, will compress the vessel, and prove that the vapour has lost its bulk by the condensation and abstraction of heat, which has thus been effected.

On these principles the condensing steam-engine is constructed, of which we shall have to speak in the section of Applied Mechanics. A vast variety of natural phenomena also depend on the laws of vaporisation and evaporation. We must defer considering these in their amplitude; for the branch of science, called Meteorology, embraces these effects.

CONDUCTION OF HEAT.

BEFORE treating on Latent Heat, we shall consider the ability which bodies have of conveying the force of heat by what has been termed "conduction."

All substances are divided by philosophers into two classes, so far as Thermotics are concerned; and these are respectively termed "conductors" and "non-conductors." Nevertheless, these distinctions are empiric; because no body can be called absolutely a good or bad conductor, the quality existing only in comparison with others relatively better or worse.

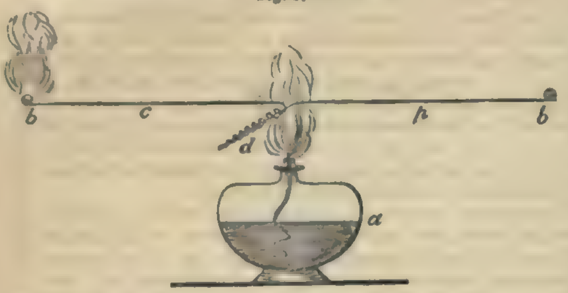
Daily life affords familiar instances wherein the properties of conductors and non-conductors are called into play. In many domestic contrivances, one part is made of a good conductor, and the other portion of a non-conducting substance. The body and handles of an urn, a tea-kettle, teapots, &c., are respectively made of metal and wood: the latter being a bad conductor, prevents the heat passing from the hot metal to the hand. An illustration of the law of conduction may be noticed in the different rate at which heat passes to the hand, from the bright metallic portion of a kettle, and that part covered with charcoal. A kettle filled with boiling water may be safely placed on the hand, if the bottom is well coated with soot, &c.

Another simple mode of illustrating the comparative power of conducting heat, possessed by different substances, is that of placing in the flame of a gas-lamp a copper wire and a rod of glass of equal size. It will be found that the heat of the flame travels rapidly to the hand by means of the metal, whilst no sensation of heat is experienced through the rod of glass. Now, because the metal conveys the force of heat rapidly, it is called a good conductor; whilst the glass, conveying the force but slowly, has been termed a bad conductor.

Even metals, which are generally excellent conductors of heat, vary very much in their power in this respect; as the following experiment will prove :—

Experiment 13.—Twist together a piece of copper and platina wire, and at the extreme free ends of each attach a piece of phosphorus. On applying heat at the point where the two metals are in contact, the heat will travel along each wire until it reaches the phosphorus. In doing so it will travel faster through the copper than through the platina wire—illustrating the fact that copper conducts heat quicker, and is, therefore, a better conductor than platina. The annexed figure illustrates the mode of carrying out the experiment.

Fig. 5.



a, the source of heat, as a spirit-lamp; *bb*, pieces of phosphorus; *c*, the copper wire; *d*, the twisted part where the metals join; *p*, the platina wire.

The wires may be held in the flame by a pair of nippers pressing the twisted part, and each wire should be of the same thickness, and, at the ends, of the same distance from the centre of the flame.

The following table illustrates the comparative conducting power of some of the metals, of which gold stands the highest, and lead the lowest, in the list:—

If Gold conducts heat at the rate of	1000
Silver ,, ,, ,,	973
Copper ,, ,, ,,	898
Platina ,, ,, ,,	381
Iron ,, ,, ,,	374
Zinc ,, ,, ,,	363
Tin ,, ,, ,,	304
Lead ,, ,, ,,	180

It will thus be found, that the conducting power of gold, silver, and copper are nearly alike; as is that of platina, iron, and zinc.

Why one solid body should conduct heat better than another, is by no means evident. It may depend on some peculiar molecular constitution of which we are ignorant. It is plain that solidity or specific gravity is not the sole cause, as, in that case, lead should be a better conductor than iron, &c. We shall have to remark on this subject when we deal with Specific Heat.

Other solids besides metals, which, as we have observed, are generally speaking good conductors, vary greatly in their powers of carrying off heat, and, for that reason, are used in daily life as economical arrangements for preventing its escape. Of these may be named earths of various sorts, charcoal, &c. Whilst gold conducts heat at a rate of 1,000, clay, in the form of brick, has but the one-hundredth part of that power, compared to the metal; hence the employment of fire-brick in the sides of furnaces, and of clay "backs" in ordinary domestic fire-grates, &c. The same principle has lately been employed in constructing fire-proof safes, which are often made of plates enclosing a comparatively non-conducting material, such as charcoal, by means of which heat is prevented from passing through and injuring the contents of such arrangements. Steam-boilers, and the cylinders and pipes of steam-engines, are covered with wood or felt, to prevent the escape of heat, and the condensation of the steam which they contain.

A very general idea of the relative conducting power of various materials, may be obtained by placing the hand consecutively on paper, wood, stone, and a metal. Each of these, although of the same temperature, will seem colder than the other, in the order we have arranged them, because they are successively better conductors of heat, and, therefore, more rapidly abstract caloric from the body. A more accurate mode of ascertaining the differences of their conducting powers, is by introducing thermometers into closed vessels coated with each material, and noticing the time required for water of the same temperature in each, in attaining one of a lower degree. Or if rods of various metals, of equal length, have one end immersed in a liquid of high temperature, and if the other end is coated with wax, the time elapsing between the melting of the wax on each end will give an approximate ratio.

The latter mode is subject to error; because, as different bodies have different capacities for heat, the length of time they require to be heated to identical temperatures will be influenced thereby.

Either method should be so tried as to avoid the effects of absorption of heat from other bodies; and unless each metal is exactly in the same state as to its external surface, error would be occasioned by its power of radiation, &c.

One of the most interesting series of facts in connection with the conducting power of solid bodies, is that which relates to the value of different sorts of clothing employed to retain animal heat; respecting which, instructive experiments may easily be tried by immersing thermometers in closed tin vessels containing water of equal temperature in each, and noticing the length of time required for each vessel, clothed externally with different materials, to come down to one standard.

It is thus found, that the following articles conduct heat in the order we have arranged them; in which the best conductor is first placed, and those of an inferior kind will be found in succession. The number indicates the time, in seconds, required for a heated body to cool to an even temperature, when coated with the substances named.

Comparative conducting power of clothing materials.

Silk twist	81″
Cotton wool	104
Wool unspun	112
Silk from the cocoon	128
Beaver, eider, and hare fur, about	130

It is thus found, that the substances with which animals are generally clothed, are the best adapted for the preservation of vital heat; and, generally speaking, the thickness of the coating is proportioned to the climate in which the animal naturally exists. The reader will not fail to notice, that the animals, birds, &c., found in northern regions, are liberally supplied with hair, wool, &c., such as the polar bear and the wild goose; whilst those existing in tropical climates, as the giraffe, &c., are supplied with but a thin coating of external non-conducting material. Man, whose intelligence enables him to adapt himself to circumstances, takes advantage of various materials for clothing purposes; and hence the employment of linen and cotton garments in the hot regions of the tropics, and the use of woollen and fur garments in colder countries.

Convection of Heat.—Liquids are, generally speaking, very bad conductors of heat, and the process of its propagation through them has been termed *convection*, because the particles move, and thereby *convey* heat with them. This is true both with respect to liquids and aëriform bodies; and we shall therefore consider them together in reference to this property.

If a solid body is heated in any part, the caloric so imparted at once travels in every direction; but that such does not occur in liquids, may at once be perceived on trying the following experiment:—

Experiment 14.—Place a metal dish, containing spirits of wine, on the surface of some water, and immerse a thermometer in the latter, so that its bulb shall rest three inches below the bottom of the metal vessel. On igniting the alcohol, the water immediately touching the copper may be made to boil, but the thermometer will not show any increase of temperature; which proves that heat scarcely passes downwards through the liquid. If heat, however, is applied at the bottom of the vessel holding the water, it will be observed that the temperature will rapidly increase, owing to the *convection* or conveyance of caloric by the particles of the expanded liquid rising to the surface.

In arranging steam or hot-water apparatus for heating purposes, this principle must always be observed. Steam and water-pipes are, therefore, placed at the lower part of a room, because the hot air they produce, being expanded, rises, and conveys with it the caloric from the heating apparatus. Ventilation is generally effected by adaptations of this principle; and, as hot air always rises, an apartment may easily be ventilated by introducing, at a low level, any source of heat. Much has been said and written in respect to the best modes of ventilation; and whilst the necessity of a supply of pure, and the removal of foul air, is universally recognised, the different means of obtaining these results have been the subjects of a large number of patented inventions.

In many of these, the projectors have lost sight of the principles, in obedience to which success can only be insured. In some instances, the supply of fresh, and the removal of foul air, are proposed to be effected by openings at the upper part of a room. Despite of the ingenious modes by which these arrangements are carried out, their success is but partial, and can never go beyond a *dilution* of the vitiated air contained in the room. We know of no experiment which more completely illustrates the true principles which should govern attempts to effect proper ventilation than the following; and a careful study of its facts will be a better guide to success than a volume of precepts :—

Experiment 15.—Place a lighted candle on the floor of a room at the open door; and, if there is no other access for air into the apartment, it will be observed that a current of cold, and therefore dense, air, on entering, will drive the flame of the candle *inwards*. By holding the candle *midway* between the top and bottom of the doorway, the flame will be quite still, because no current of any kind exists in that position. If the candle is held so as that its flame shall be near the *top* of the door, it will be observed to be driven *outwards*, because thence the hot and lighter air makes its escape.

Following these principles, it is evident that a supply of pure air must be made at the lower part of an apartment; and an escape for hot air should be arranged for at the top, or near the ceiling, of a room. Within the last few years, openings, concealed by ornamental work, have been made in most of the rooms of new houses; and, by communicating with the open air, they permit the escape of noxious products, and so ensure, to some extent, an amount of ventilation.

It is impossible here to trace the variety of interfering causes which oppose the application of such principles in general practice; but, in most cases, such may be overcome by attention to the rules we have laid down; and just so far as natural effects are imitated, so success will attend endeavours of this kind.

A very interesting series of effects has been lately brought to light; all of which relate, more or less, to the laws of the conduction of heat by liquids and vapours. We refer to the peculiar state which a liquid acquires when placed in contact with a surface heated considerably beyond its boiling point, and which has, to some extent, explained the reason of boiler explosions in instances wherein no other cause could be assigned.

If cold water is allowed to come in contact with metal heated to 200° or 300°, the liquid is speedily converted into vapour, because the heat from the metal is rapidly communicated to it. If, however, the metal is heated to a temperature approaching red-heat, the same result does not take place—the liquid, in fact, will run off the surface, just as mercury leaves a sheet of glass on being poured thereon. The effect is termed the spheroidal state, and only occurs when a stratum of steam or air exists between a surface and a globule of liquid. Something of an analogous kind occurs when water is cast on to the feathers of a bird; or, as may be often observed, in the case of the dew on leaves; which, running over them, is nevertheless not in contact with them.

If a vessel of copper, &c., is made red-hot, and cold water is poured into it, some time will elapse before the liquid will boil, because a film of steam is formed, which prevents the conduction of heat between the metal and the liquid. If, however, the vessel is allowed to cool, the liquid will flash into steam so soon as a lower temperature is arrived at. It will be seen, therefore, that vapour is a worse conductor of heat than the liquid from which it has been formed.

Now, steam-boiler explosions may, in many cases, be explained on the principle here named. In almost every instance, the water supplied to steam-boilers contains earthy matter, such as lime, &c.; and, in the process of time, this forms a "fur" on the shell of the boiler. The fur being a bad conductor of heat, permits the metal of the boiler to become red-hot, and this often causes the earthy matter to "chip" off, and thus leaves exposed the red-hot metal, apparently in contact with the water. For some time no extraordinary effect results; but if a supply of cold water is sent into the boiler, the metal gradually cools down, and the stratum of steam, which had kept the liquid from touching the metal, being removed, an immense evolution of steam takes place, and an explosion of course at once ensues. An inexperienced person would at once suggest the extinguishing of the fire as the best course in such circumstances; whereas, strange to say, the only safe plan is to increase the heat until all the water can be removed from the boiler by means of a valve, &c. By such a course the intermediate stratum of steam is maintained, and risk of explosion is diminished.

By forming a stratum of vapour by means of sulphurous acid, M. Bontigny was the first to show that water could be frozen in a red-hot platina crucible. As the repetition of this experiment is by no means easy to many persons, we suggest one which may easily be tried, and which fully illustrates the principles to which we here allude. It is that of handling red-hot lead, without risk of injury to the operator.

To do this safely, the hand must be perfectly clean, and must be coated with a "skin" of steam. This is best effected by washing the hand in some strong liquid ammonia, which, by its alkaline action, removes all grease, &c., that would otherwise prevent the moisture from completely wetting its surface. The lead should be red-hot; as, if used at a lower temperature, severe injury might be sustained. The best manner of trying this singular experiment, is to pour the liquid ammonia (liq. ammon. forts. of the shops) into a basin, whilst an assistant presents the lead in a ladle. The hand is first to be carefully washed in the liquid, and may then be introduced into the red-hot metal. Any quantity may thus be cast into a pail of water; and, having repeatedly tried the experiment, we may say, that the only inconvenience which we have sustained is, that the hand becomes gradually cold, and sometimes painfully so, if the experiment is much extended.

Few persons have nerve enough to try this; but there is no danger, providing the precautions we have named are fully attended to. If, however, the lead is not very hot, it may solidify round the fingers, and so produce great inconvenience.

A similar experiment to the above is that of walking on red-hot iron—the feet being prepared in a similar manner; or they may be coated with a skin of glue and sand, which, as a non-conductor, will effectually prevent injury to them.

Daily life presents us with innumerable instances wherein the conduction or non-conduction of heat is taken advantage of. Metallic vessels, because of their good conducting powers, are employed for the purpose of heating liquids for manufacturing and domestic purposes; whilst the interposition of non-conductors—such as the glass or wooden handles of teapots, the cover of felt to the cylinder and boiler of the steam-engine, and numerous similar contrivances, are used for an opposite purpose. In vegetable life, we have the bark of the tree; in animal life, the skin or wool over the flesh—each of which, as a comparatively bad conductor, retains the vital heat of either system. The thick coating of snow which falls during winter, has the effect of preventing the destruction of vegetable life, through being a bad conductor of heat. The cells of the plant, which would otherwise be burst by the expansion of the ice, are thus preserved uninjured, and their delicate organisation maintained till the returning spring. Thus, in this, as in every other instance of natural laws, we find one cause having a universal and beneficial operation in its varied relationships.

Having thus spoken of the effects of sensible heat, we next proceed to a subject of great interest, wherein caloric will be considered in its latent or hidden state.

LATENT HEAT.

CONSIDERABLE difficulty is often found by those not far advanced in scientific study, in understanding the doctrine of *latent* forces; and before proceeding to investigate the theories and facts respecting latent heat, it will therefore be convenient that we should define our meaning of the term.

Those powers or forces which are evident to, and perceived by, the senses, are termed *sensible*, their presence being easily recognised; but in all matter there also exist forces which are not perceptible to the senses, until proper means are employed to call them forth. Thus, no one could predicate, by simple inspection, that a common match contained the forces of heat and light, although it is well known that friction easily educes them.

It is manifest, that caloric, or its proximate cause, must, although unperceived, exist in a body; because, as we can create nothing, we can only call out that which really, although imperceptibly, is present. Now forces thus disguised are called *latent*, because they lie hid, until called forth by special means. We have chosen a familiar illustration of the meaning attached to the term latent; but we must give this a general signification, by stating that all substances contain heat, light, &c., in a hidden state; and this is true even in those least likely to afford them.

Ice would, at first sight, appear to be the most unlikely body from which heat could be obtained; but nothing is more easy than to produce such a result, as the following experiment will prove:—

Experiment 15.—Make a hole in a piece of ice, and, into this, introduce a pea of the metal potassium. Owing to the chemical action which will take place, both heat and light will be rapidly evolved.

From this instructive experiment, we learn that both heat and light must exist in a latent state; and, in this instance, chemical action is employed to render these forces sensible. Our introductory experiments on the production of heat are examples of a similar kind.*

It is owing to heat being present in a latent form, that gases exist; and hence, when gases, vapours, and liquids are reduced to the solid state, they invariably give out heat; and, *vice versâ*, when solids are converted into liquids or gases, they absorb sensible heat, which afterwards becomes latent. On compressing air in a vessel by means of a syringe, the metal of the vessel generally becomes quite hot, owing to the air forced in losing a portion of its latent heat. When the air is allowed to escape, it will be found that the reverse effect is produced, and the vessel parts with heat, and becomes cold to the touch. If a bottle containing soda-water, of the temperature of the air, is suddenly uncorked, and its contents are poured into a vessel containing a thermometer, the abstraction of heat, produced by the expansion of the carbonic acid gas, will be made evident by the mercury of the thermometer at once falling.

The amount of latent heat in various vapours differs materially; and the latent heat of steam exceeds that of any other. This will be evident from the fact, that it requires 5½ times as much heat to convert a given quantity of water into steam, as it does to heat the same quantity of water from freezing to boiling point.

Again, steam, on being reduced to the liquid state, parts with the heat it had previously received, which passes into a latent form; and hence, a pound weight of steam would heat 5½ pounds of cold water to a temperature of 212°. The reader will here perceive another proof of what has been already stated—that gases and vapours owe their condition to the force or agency of heat.

If we examine the effect of mixing water of two different temperatures in equal quantities, we shall find that the resulting temperature will be increased just half of the excess of the highest. Thus the addition of one pound of water, at a temperature of 100°, with one pound at 32°, will give a mean temperature of 66°. If, however, equal weights of ice and hot water are mixed together, the resulting temperature will not be a mean between the two; for it will not exceed 32° until the whole ice is melted. The heat of the hot water thus assumes a latent form, and is employed in liquefying the ice; or, in other words, in imparting sufficient heat to enable it to assume the liquid state. As an illustration of this, we may state that, if a pound of ice at 32° is mixed with a pound of water at 172°, the difference of 140° will be apparently lost in converting the ice into water.

The following table, collected from the investigations of Dr. Ure, represents the latent heat, at the boiling point, of

Water, as equal to	1000°
Alcohol, s. gr. 0.825 . . .	457°
Sulphuric ether	312.9

The abstraction of its latent heat, and the conversion of water into ice, may be easily effected by means of rapid evaporation, by the air-pump, or in an instrument called the Cryophorus, or "frost bearer."

Experiment 16.—Fill a watch-glass with water, and on the surface of the liquid place another watch-glass filled with ether. On introducing these into the receiver of an air-pump, and exhausting the air in the usual manner, the rapid evaporation of the ether will abstract the latent heat of the water, and will convert it into ice. Generally speaking, the two glasses become solidly frozen together.

This peculiar mode of producing cold has been lately employed on a large scale, for the purpose of producing ice in tropical countries. Special arrangements are employed for recovering the ether, which may thus be repeatedly used, and the economy of the process maintained.

Experiment 17.—The Cryophorus is made by blowing a bulb at each end of a long glass tube. One of the bulbs being filled with water, heat is applied thereto, so as to expel all air, and the vessel is then hermetically sealed. For the purpose of this experiment, the whole of the water is retained in one bulb, and the empty one is immersed in a mixture of snow or pounded ice and salt. This reduces it to a temperature of 0° Fahrenheit. In a very short time the water in the other bulb will be converted into ice, owing to the rapid evaporation and loss of latent heat which it sustains.

By the abstraction of latent heat, a great degree of cold may be produced—hence the employment of freezing mixtures, for the purpose of cooling wines, &c. Whilst these assume the liquid state, they abstract the latent heat of bodies immersed in them. A well-known instance of this is the use of salt for the purpose of removing ice and snow from foot-paths. In the employment of these means, the snow, &c., melts, and a great decrease of temperature results. The practice, for this reason, is highly to be reprehended, because it is injurious to health. Persons treading in a mixture of this kind sustain a great loss of natural heat from the feet; and to so great an extent does this take place, that the leather soles of shoes, if thus moistened, will, for the reasons we have named, become the cause of dangerous diseases, such as fever, diphtheria, &c. The following are mixtures which may be employed for the purpose of producing intense cold.

Experiment 18.—Mix together equal weights of sal-ammoniac and nitre, both in fine powder. Place the mixture in a tea-cup, and, having added cold water, stir the whole by means of a thin test-tube holding cold water. In a short time the liquid in the test-tube will be completely frozen, owing to its latent heat being abstracted during the solution of the salts external to it.

Experiment 19.—Mix equal weights of snow or pounded ice and chloride of calcium, in the dry state. If mercury, in a test-tube, is introduced into this mixture, the metal will be frozen, owing to the intense cold produced.

Experiment 20.—Place a small piece of lint or cotton wool on the bulb of a thermometer, and moisten it with a little ether or sulphide of carbon. The evaporation, which will thus take place very rapidly, causes the mercury of the thermometer to fall, sustaining, as it will do, a loss of latent heat.

---

* See *ante*, p. 15.

Without multiplying instances of this kind, we may refer to an extended application of the principle in the condenser of the steam-engine, and the ordinary process of distillation. With respect to the mechanical details of the arrangement used for the former purpose, we must defer any detailed description to the section on Mechanical Philosophy, wherein the subject will be fully dealt with. The steam, after exercising its force on one side of the piston, is ejected into the condenser, which is an air-tight vessel, surrounded by a cistern of cold water. A jet of cold water plays into the condenser, and, immediately on the steam entering, its latent heat is abstracted by the cold water, and it suffers condensation, suddenly contracting to a bulk of $\frac{1}{1700}$th part of that which it occupied in the state of vapour. To the researches of Dr. Black and James Watt, this application of the laws of latent heat is chiefly due.

In the process of distillation, heat is applied for the purpose of converting a liquid into the state of vapour, and of thus separating it from others with which it had been previously mixed. The vapour thus formed is again condensed by passing it through a metal worm surrounded with cold water.

In the ordinary process of manufacturing spirits, stills of great size are employed, and they are generally made of copper. The "wash," or mixture, formed by infusing malt, and fermenting it with yeast, is introduced into the body of the still, and, heat being applied, the spirit, which boils at a lower temperature than water, passes over into the worm; and, being there condensed, it reassumes the liquid state. The stills and general arrangement vary in shape, &c.; but a common tea-kettle, to which two or three feet of metal tubing has been attached at its spout, will illustrate the whole principle of the process. The mechanical arrangements alone vary from this simple mode of distilling, when adopted by the spirit distiller.

The latent heat of vapour seems to vary as the temperature is increased; but the differences hitherto ascertained do not warrant any reliance on their accuracy.

A very common application of the laws of latent heat is that of drying and warming by means of steam conveyed through pipes. Owing to the latent heat of steam being so great, it may be made a vehicle to carry heat to a great distance from its source; and it must be borne in mind that steam will heat six times as much space (nearly) as a piece of metal of the same weight and sensible temperature. Hence its employment for manufacturing purposes, especially in bleaching, dyeing, calico-printing, paper-making, tallow-melting, &c. It is usual to cover the pipes conveying the steam with felt, until they arrive at the spot where heat is required, where of course they are left uncovered, so that the heat may freely pass off. Steam is an economical agent for warming apartments, and exceeds in this respect water, when similarly applied; because, whilst the water only gives up an amount of heat equal to the difference between its own temperature and that of the air of the apartment in which it is employed, steam affords also its latent heat, and, therefore, more entirely and conveniently answers the purpose.

On placing the hand over a jet of steam proceeding from a boiler, it will be found that the higher the pressure under which the steam escapes, the lower will its sensible temperature appear. At first sight this seems paradoxical, but the difficulty at once disappears on applying the laws of latent heat to its explanation. Of course, as the steam rushes out of the jet, it must expand. In so doing, it robs the surrounding air of heat, so as to permit of its expansion; and hence, the stronger the pressure of emission, the cooler is the blast. When tried with a pressure of 120 pounds on the square inch, the jet of steam seems to have the same effect on the hand as a jet of cool air. A vacuum is also formed during this expansion, and a ball of wood may be thus kept playing in a jet of steam for any length of time.

The abstraction of latent heat, together with pressure, has been applied by Dr. Faraday and others to the liquefaction of gases. Of all experiments of this kind, the condensation of carbonic acid gas has been the most successful. The gas is manufactured on a large scale, in a strong metallic vessel, and is then allowed to pass into a receiver. On issuing from a jet placed in the side of the receiver, the gas expands so rapidly as to produce intense cold, and undergoes congelation. A very usual course adopted to liquefy some gases, is to enclose the materials from which they are procured in a strong glass tube, bent at an angle at its centre. Each end being hermetically sealed, the gas is received in the liquid state in that end opposite to where it is being produced. By these means, carbonic acid, cyanogen, &c., have been obtained in the liquid state.

If a jet of air issuing from an orifice under a pressure of 60 to 100 pounds on the square inch, is allowed to impinge on a good conductor, its moisture will be immediately frozen. In some deep mines in Germany, where air is pressed by a high column of water for the purposes of a blast, it is no uncommon occurrence to observe snow produced from the moisture of the air issuing from the pipes, or from any crack in the arrangement; and it is the custom of the miners to place their caps against the jet, for the purpose of showing the effect to the visitor.

SPECIFIC HEAT.

It has been already stated, that if equal quantities of water, at different temperatures, be added together, the resulting temperature will be a mean between the extremes. But that result will not occur when liquids of different kinds are similarly mixed. Thus, if mercury and water, at different temperatures and in equal weights, be added to each other, the resulting temperature will be nearer that of the water, presuming that to have been the hottest of the two liquids.

This fact has given rise to the term *Specific Heat*, which means that different bodies have various capacities for heat—some requiring more, and some less, of sensible heat to raise them to an equal or standard temperature. The ratio of these capacities is found by mixing liquids, &c., at different temperatures, and noticing that which results from the mixture; and, in most cases, the specific heat, or capacity of water for heat, is adopted as the standard.

The best illustration of the mode usually adopted, may be found by taking mercury as the type of other bodies; and we shall thus be able to explain the general law which governs all matter with respect to its capacity for heat.

If one pound of mercury, at a temperature of 40°, be mixed with a pound of water at 100°, the resulting temperature of the mixture will not be a mean between the two, but will be found to be 97½°. Thus the heat of the mercury will be raised about 57½°; whilst the water will be reduced in temperature to the extent of 2½°.

Now, putting these figures into the ordinary form of proportion, we have

$$57.5^\circ : 2.5^\circ :: 1 : 0.04348.$$

In which 57.5° represents the number of degrees by which the temperature of the mercury is raised; 2.5° the loss of heat sustained by the water; and 0.04348 is the specific heat of mercury compared to water, as the standard, or 1.00000. The figures here obtained are somewhat too high; but the illustration will give an insight into the means usually employed for the purpose of obtaining the specific heat of bodies. The plan is varied with solids; but the principle is still the same.

The following table gives the specific heat of some bodies, water being the standard:—

Water	1.000
Alcohol	0.660
Iron	0.114
Copper	0.095
Zinc	0.095
Platina	0.032

The student will find considerable difficulty in reconciling the laws of latent and specific heat with those of the undulatory theory (which we entered into at the commencement of this section), more especially if he observe such phrases as "the *quantities* of heat which a body contains;" which are often employed in treatises on this subject. It is true that these are only used to popularise our ideas; but still there will be a tendency to take a material view of the nature of heat whilst experimenting with the force; and this will be, to some extent, confirmed when the effects of specific and latent heat are kept alone in view. Theories, however, are valuable only so far as they generalise numerous facts; and the undulatory theory is insisted upon by philosophers, because it collects under one broad view a chain of allied causes. In its application to the branch of Thermotics, with which we are now dealing, many difficulties arise, which cannot be cleared up until our researches have been so far extended as to give a greater insight into the nature of heat, &c., than we at present possess. When we refer to radiant and polarised heat, the value of the undulatory theory will be at once perceived, because we shall be able to range so many phenomena under one comprehensive idea.

Whatever theory is employed to connect the various facts of Thermotics, it is evident that the actual amount of caloric in any body cannot be measured; and that the specific heat of any substance is merely a term signifying its relative power of absorbing the force as compared with that possessed by other bodies. There is, however, a very singular relation existing between the atomic weight, or combining proportion, and the specific heat of many substances.

In our prefatory remarks, we stated that all matter is composed of atoms; and by examining the chemical relationship of these atoms, we find that they have a tendency to combine in certain proportions only, and every elementary body has accordingly had assigned to it a number which expresses the relative value of its power of combination. As an instance of this, the analysis of water shows that eight parts, by weight, of oxygen combine with one part of hydrogen, and, by their union, nine parts of water are produced. These numbers are called the equivalents, atomic weights, or combining proportion of these gases; and it is with these relative weights that the specific heat of a body seems to have some relation in certain instances. If, for instance, the number 3.1 is divided by the number expressing the specific heat, say of iron, zinc, or copper, we find that the quotient very nearly corresponds with the atomic weights or equivalents of those metals when expressed in a series of which that of hydrogen is unity. This will be observed by the annexed table.

Specific heat of		Calculated Equivalent.	Equivalent obtained by Chemical Analysis.
Iron	0.114	27.2	28.0
Copper	0.095	32.6	31.7
Zinc	0.095	32.6	32.0

These relationships are, however, by no means so evident in other bodies, although, generally speaking, the product of the specific heat and the atomic weight is either nearly a constant sum or one which is a multiple thereof. In this, as in many other connections of different phenomena, we meet with difficulties which prevent our affirming the existence of a law of which we have as yet but a glimpse.

We have hitherto referred solely to the specific heat of solids and liquids; and, with respect to gases, the information which has been obtained is by no means satisfactory. This is chiefly owing to the difficulty which exists in carrying out the investigations in an accurate manner, in any case, with aëriform bodies. This is generally done by passing the gas under examination, at a certain temperature, through water, also of a known temperature; and, in proportion as the heat of the liquid is raised by the same bulk of each gas, their relative capacity for heat is ascertained, and the specific heat arrived at.

RADIATION, ABSORPTION, AND REFLECTION OF HEAT.

Having directed attention to the leading facts which the study of sensible, latent, and specific heat affords, we proceed to consider those phenomena which present themselves when rays of heat are emitted from a central source.

The intensity of all radiant forces is diminished in a geometrical ratio as the centre of force is departed from; and it is found that this intensity is inversely as the square of the distance. The student will, perhaps, more readily understand this by placing before a candle-flame a square piece of cardboard, of any size. If this gives a shadow of one foot square at a distance of a foot from the source of light, then that shadow will cover an area of four square feet at double the distance, nine square at three times the distance, and so forth. The intensity or amount of light will diminish in the same ratio as the space over which it spreads is increased. The law holds good with respect to gravitation,* light, electricity, magnetism, and other central forces. So far as heat is concerned, we shall at present confine our attention to its radiation through air; because, like light, it suffers both refraction and polarisation when it is passed through certain media—subjects on which we shall subsequently dwell.

Bodies vary much in their power of radiating heat; and those having a dark and rough surface hold the highest place in the scale. Pointed surfaces especially fall under this class, whilst polished ones scarcely radiate heat at all.

Absorption is a property by which bodies are enabled to take in heat from any source, and thus have their temperature rapidly raised. Generally speaking, good radiators are also good absorbers, because each effect is due to a similar state of the body under examination. Of this class are lamp-black, cloth, and bodies of a dark colour; and the truth of this will be at once made evident by the following experiments:—

Experiment 21.—Inclose a thermometer in a metal cylinder which has a polished external surface, and introduce one into a vessel which has been blackened by means of lamp-black and glue. Fill these with water, and expose them to the action of the rays of the sun. It will be found that, owing to the blackened surface, the rays of heat will be rapidly absorbed, and the temperature of that vessel will quickly rise. In the one having a polished surface, very little change of temperature will be produced, because the rays of heat are reflected, and therefore not absorbed.

Experiment 22.—If the two vessels are exposed in the open air on a clear night, it will be found that the temperature of the blackened vessel will speedily fall, owing to the loss of heat caused by radiation, whilst that of the polished surface will scarcely be affected.

Hence we find that good radiators are good absorbers, and that bodies having a polished surface reflect heat freely, but neither radiate nor absorb it to any extent. The best radiator, such as lamp-black, will emit eight times as many rays in the same period as a polished surface, such as a silver plate would do under the same circumstances.

A great variety of interesting phenomena in nature depend on these laws of radiation, &c. Dew is formed owing to the radiating power of the earth's surface; and if a thermometer is placed at night on a grass-plot, when the sky is quite free from clouds, the temperature indicated will be much below that shown by a thermometer raised a few feet from the ground. The radiation of heat thus cools down the temperature of the surrounding air, and the moisture, being condensed, falls down and rests on the surface of plants, grass, &c.

The temperature at sea is always higher at night-time than on land, because the level surface of the water is a bad radiator. The peculiar effect of the sea and land breezes is owing to the changes resulting from the radiating and absorbing power of the earth's surface. During the day-time, the ground becomes warmed by the absorption of the rays of heat, and thus an upward current is produced, the sea air rushing in to supply the partial vacuum formed. After sunset, the reverse effect takes place; the earth then commences to radiate heat, and, becoming cooler, the air sets towards the sea, and hence the production of the land-breeze. The following extract from a work by Captain Maury, entitled *The Physical Geography of the Sea* (Jan., 1861), will be read with interest, as affording full confirmation of these applications of natural laws.

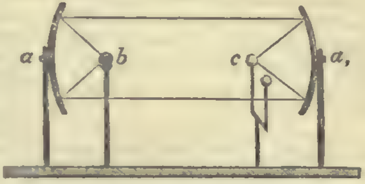
---

* See Introductory Chapter; p. 3, *ante*.

Speaking of the country near the coast, in hot climates, Captain Maury observes—"The inhabitants of the sea-shore, in tropical countries, wait every morning with impatience the coming of the sea-breeze. It usually sets in about ten o'clock. Then the sultry heat of the oppressive morning is dissipated, and there is a delightful freshness in the air, which seems to give new life to all for their daily labours. About sunset, there is again another calm. The sea-breeze is now done, and in a short time the land-breeze sets in. This alternation of the land and sea breeze—a wind from the sea by day, and from the land by night—is so regular in intertropical countries, that they are looked for by the people with as much confidence as the rising and setting of the sun. In extra-tropical countries, especially those on the polar side of the trade winds, this phenomena is presented only in summer and fall, when the heat of the sun is sufficiently intense to produce the requisite degree of rarefaction over the land. This depends in a measure, also, upon the character of the land upon which the sea-breeze blows; for when the surface is arid, and the soil barren, the heating power of the sun is exerted with most effect. In such cases, the sea-breeze amounts to a gale of wind. In the summer of the southern hemisphere, the sea-breeze is more powerfully developed at Valparaiso, than at any other place to which my services afloat have led me. Here, regularly in the afternoon, at this season, the sea-breeze blows furiously; pebbles are torn up from the walks, and whirled about the streets: people seek shelter; the Almendral is deserted, business interrupted, and all communication from the shipping to the shore is cut off. Suddenly the wind and the sea, as if they had again heard the voice of rebuke, are hushed, and there is a great calm." He also remarks—"Within the tropics, however, the land and sea breezes are more gentle. The oppressive heat of the sun and the climate of the sea-shore is mitigated, and made both refreshing and healthful by the alternation of those winds, which invariably come from the coolest place, the sea, which is cooler by day, and the land, which is cooler by night. About ten in the morning, the heat of the sun has played upon the land with sufficient intensity to raise its temperature above that of the water. A portion of this heat being imparted to the superincumbent air, causes it to rise, when the air, first from the beach, then from the sea, to the distance of several miles, begins to flow in with a most delightful and invigorating freshness."

The phenomena of the radiation and reflection of heat, may be conveniently examined by employing two parabolic metal mirrors, which must be highly polished. They may be from eight to twelve inches in diameter, and should be fixed on stands of exactly equal height, so that a straight line passing from one shall be in a line with both their axes or centres. They may be made of polished tin, or sheet zinc; perhaps the latter is to be preferred, as being more readily beaten into the proper shape. They may be polished by means of rottenstone and oil, and should be finished with tripoli, rubbed on by means of cotton wool. Their focus is found by placing a candle-flame some distance from the reflecting surface; and if a piece of smouldering brown paper is held so that the smoke shall rise between the light and the reflector, the focal point will be at once observed as that place where all the rays passing from the reflector meet together. In the focus of one of the mirrors, the source of heat is placed on a stand; and, in the other, the thermometer which is employed to indicate the reflected heat. Fig. 6 represents a pair of these reflectors, arranged for the purpose of an experiment.

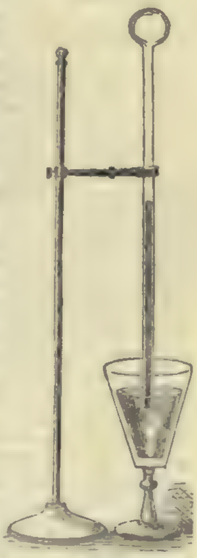
Fig. 6.



a a, represent two metallic reflectors; *b*, the source of radiant heat, as an iron ball; *c*, a differential thermometer. The rays of heat proceeding from *b* are reflected to *a*, and thence to the bulb of the thermometer at *c*, in the course indicated by the lines.

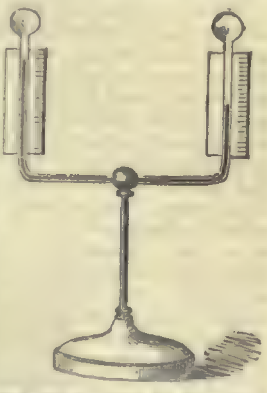
An ordinary mercurial or spirit thermometer may be used for many experiments, its bulb of course being placed in the focus of the mirror. For delicate experiments, however, an air thermometer must be employed. A simple one may be constructed by filling a thermometer tube with any coloured liquid, and then inverting the stem in a vessel of water. When so inverted, sufficient liquid should be allowed to escape, so that the bulb may be full of air, because it is by the expansion of the air that the presence of heat is manifested, and which also drives down the liquid in the stem. One of these thermoscopes, as they are generally called, is represented in Fig. 7.

Fig. 7.



For many experiments on radiated and reflected heat, an instrument, constructed on similar principles, but having two bulbs, is always employed. This is the invention of Sir J. Leslie; and it is exceedingly sensitive in indicating minute changes of temperature. It consists of two bulbs, each containing air, which are joined by means of a glass tube, nearly filled with any coloured liquid. The tube is bent into two arms, one of which is graduated. In using the instrument, one of the bulbs only is brought towards the source of heat, and that should be the graduated one. Its action is due to the expansion of the air in one bulb, and the consequent compression of that in the other; and according to the depression of the fluid in the graduated limb, so the amount of sensible heat is measured. When employed in one of the reflecting mirrors, the bulb attached to the graduated limb is so placed in the focus of the reflector, that the other may be removed to one side; the latter is thus not influenced by the reflected heat. The annexed engraving illustrates the usual form of one of these instruments; and *c*, Fig. 6, shows one in use.

Fig. 8.



The following experiments will give an idea of some of the most interesting facts, both as regards radiating and reflecting substances:—

Experiment 23.—Place in the focus of one mirror an iron ball, previously made red-hot; and in the focus of the other mirror, a thermometer bulb, which should be blackened, may be introduced. The heat reflected from one mirror to the other, and thence to the thermometer, will be evident by the mercury rising. The air thermometer is preferable for these experiments. That it is not the mere radiation of the heat from the ball which produces the effect, is certain, because the mirrors may be removed a considerable distance from each other, and yet the mercury of the thermometer will rise, under the circumstances above-named. By means of two mirrors, each six feet in diameter, and about ninety feet apart, we have seen a piece of meat cooked by the reflected heat of a gas jet.

Experiment 24.—If the bulb of the thermometer is retained, as in the last experiment, and if the mirror before which the ball of iron is placed be coated with lamp-black, it will be found that no heat is then reflected thereby, because the blackened surface absorbs the heat, and is, therefore, incapable of reflecting it.

It will thus be seen how the power of reflecting and absorbing heat may be produced in a body by merely changing the character of its external surface; and, in obedience to these laws, a great variety of instructive experiments may be tried.

By way of parenthesis, we would remark, that the abstract teachings of science are valuable only so far as they give us an insight into natural laws, and assist us to make such applications of them as may conduce to intellectual progress and social benefit. In every case, however, these lessons so taught can only be appreciated and rendered of service in proportion to the intelligence of the student. Having this object in view, we shall suggest a few experiments which, whilst they may still further elucidate the special laws to which we now refer, will also give a wide field for the exercise of the ingenuity of the experimenter, so far as their application to the purposes of daily life are concerned.

Experiment 25.—Instead of the iron ball mentioned in Experiment 23, place a tin vessel, having one side white, another polished, and one blackened, in the focus of one of the mirrors—retaining the thermometer in the focus of the opposite mirror. The vessel is then to be filled with boiling water, and must be closed at the top, so as to prevent the escape of heat. It will be found, on presenting the polished or white side to the mirror in whose focus it stands, that the vessel will scarcely radiate any heat so as to be apparent by the rise of the mercury in the thermometer; whilst the blackened side, if similarly placed, will radiate considerable heat, which, by reflection from the mirror, will immediately raise the temperature as indicated by the thermometer.

The employment of dark-coloured substances for absorbing and radiating heat is thus accounted for; and one well-known instance, where the opposite character of an absorbing and reflecting or non-radiating material is often used in one vessel, is that of the common tea-kettle, whose lower side, in contact with the fire, absorbs heat rapidly when coated with charcoal, whilst the polished surface prevents the escape of heat by its non-radiating nature. For similar reasons, a polished metal teapot will retain heat longer than a dark stone one. If, however, the latter is placed near the fire, this difference will not be so evident, because the absorbing power of the stone vessel will be exercised, and the heat apparently retained, although it really is being continually received, and so counterbalances the radiating power of the material.

Experiment 26.—Place pieces of cloth of different colours on snow, so that the sun's rays may shine directly on them. It will be observed, that the darker the colour of the cloth, the more heat will be absorbed, and the deeper the cloth will sink in the melted snow. Hence, dark-coloured cloths are warmer, as a clothing material, than those of a light colour, because they absorb more of the heating rays of the sun.

Experiment 27.—Place a thin covering of any kind over a shrub, so as to prevent the radiation of its heat during the night-time. On removing it next morning, no dew will be found beneath. The clouds act in precisely the same way, and prevent the formation of dew, by impeding radiation; hence dew is never formed during cloudy weather.

Experiment 28.—Having blackened the bulb of the thermometer employed in the focus of one mirror, place a piece of ice in the focus of the other one, and carefully adjust both, so that they shall be exactly opposite to each other. If this experiment is carefully performed, the latent heat of the mercury of the thermometer will be reflected to the opposite mirror, and will be again reflected to the ice, which it will eventually melt. This is a highly instructive experiment, and illustrates the action of the reflected latent heat of a body when its sensible heat appears to be comparatively low, or at natural temperatures.

The different effects of reflection, radiation, and absorption, are often observed in daily experience. Chalk rocks, for instance, reflect heat; whilst trap and other dark-coloured strata absorb it rapidly. In passing between walls which have been painted black, the radiation of heat, previously absorbed, is very great. Dark soils, for similar reasons, more rapidly change their temperature than those that are light-coloured, and the atmospheric heat thus varies considerably, under such circumstances, over their surfaces. Some very ingenious applications of the laws of radiant heat are made for domestic purposes, amongst which may be named the American oven. One side of this being made of rough metal, absorbs heat; whilst the other, being polished, reflects it: the conjoint action of these makes the contrivance an exceedingly valuable and economical one for baking purposes.

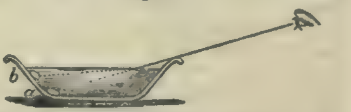
REFRACTION OF HEAT.

In our last section, we presumed that the whole of the heat radiated from a body passes to any object at a distance from it, without sustaining any loss from its absorption by the atmosphere. It is, however, found, that gases, liquids, and solids prevent the passage of a portion of the rays emitted from a heated body; and some substances have the power of bending rays of heat from what would otherwise be their natural course. Those bodies which but slightly prevent the transmission of the rays of heat, have been termed "diathermanous."

As some little difficulty may arise as to the meaning of the term "refraction," we suggest a simple experiment, which will at once illustrate its purport with respect to light; and, as heat is subject to similar laws, the student will easily perceive the nature of the refraction of either force.

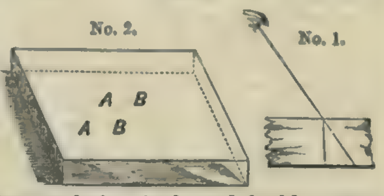
Experiment 29.—Place a shilling in a basin, and retire from it until the edge of the coin is but just visible. If an assistant now fills the basin with water, the whole of the coin will appear in sight, owing to the bending, or refraction, of the rays of light. The effect is illustrated in the annexed engraving, where *a* represents the real place of the coin, and *b* its apparent position.

Fig. 9.



The above is an instance of what is termed *single* refraction. Light and heat also undergo *double* refraction in some circumstances; and the effect with respect to light is easily observed, by placing a rhomb of Iceland spar on a line drawn across a piece of paper. The crystal, having the power of double refraction, will exhibit the line in a double appearance. Fig. 10 represents this effect, where No. 1 is a piece of spar, through which the letters appear double; and No. 2 illustrates the separated rays of light passing through the spar, and thus, also, the nature of the refractive effect.

Fig. 10.

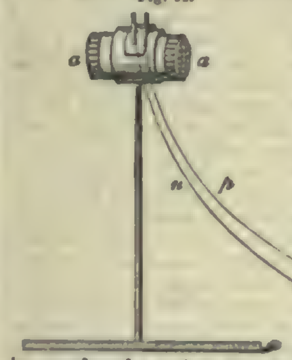


Having thus illustrated the single and double refraction of light, we proceed to examine the analogous changes which the rays of heat undergo when passing through various media.

It is necessary to bear in mind, that heat alone, and heat combined with light, pass through bodies in by no means the same degree. Thus the heat from a gas-light will pass through a plate of glass; whilst that emanating from a metal heated *below* redness, is entirely stopped in its passage. Indeed, it would seem that heat passes through solid transparent bodies just in proportion as it is accompanied by light; for the heat of red-hot coke will scarcely pass through thick glass; whilst that produced by the electric light is transmitted to a large extent. A plate of alum entirely prevents the transmission of non-luminous heat. It has been found, by the researches of Melloni and other philosophers, that rock-salt is the most permeable to rays of heat, allowing more than twice as many to pass through as plate-glass. This substance is therefore chiefly employed in experiments in connection with the refraction of heat. An instrument of a very delicate kind is employed in these experiments; which we shall but briefly describe, because the philosophy of its action will be fully investigated under the head of Electro-Magnetism.

If two metals, such as antimony and bismuth, are arranged together in bars (one of each metal being soldered to the other), and if wires are brought from the last bar of each, so as to traverse over a magnetic needle, a current of electricity will pass if either end of the bundle of bars is heated: and a current thus generated by the force of heat, will, if present to but a slight extent, affect the needle of a galvanometer, which will be instantly diverted from its usual position. This arrangement is much more sensitive of thermal changes than either the mercurial or air thermometer, and thus is invaluable in researches where small disturbances of temperature have to be measured. It is called the thermo-multiplier, and its arrangement is represented in Figs. 11 and 12.

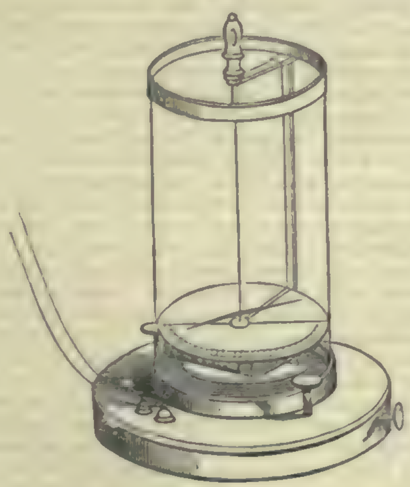
Fig. 11.



To illustrate the construction and use of the instrument, we give three engravings. In Fig. 11, we observe the thermo-electric battery—*a* consisting of bars of antimony and bismuth, from which proceed two wires, *n*, *p*. These are connected with binding screws attached to the galvanometer, represented in our next illustration.

The rays of heat being received at the end of the arrangement of antimony and bismuth bars, a current of electricity is thereby produced; and if this is allowed to pass through a wire coil, alternately wound over and under an ordinary compass-needle, and yet not touching it, the electricity will diverge the magnetic needle just in proportion to the strength of the current; and hence the amount of radiant heat may be measured by the deflections of a galvanometer. One of these is illustrated in Fig. 12, in which we observe a magnetic needle suspended over a coil placed just beneath it. The wires proceeding from the thermo-electric battery, are observed on the left hand of the engraving.

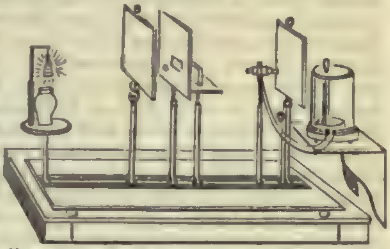
Fig. 12.



When this instrument is employed for the purpose of ascertaining the amount of heat radiating from a body, or in researches on the laws of the refraction and polarisation of heat, the arrangement illustrated in Fig. 13, is adopted; wherein we observe, on the left hand, the source of heat; in the centre, are diaphragms, through which the rays of heat may be passing; and on the right hand side are placed the thermo-electric battery, and the galvanometer, by means of which the intensity of the calorific rays is measured.

As we have already remarked, this instrument is the most sensitive which we can employ for the purposes we have named; and it has been of essential service in all researches having for their object the detection of minute changes of temperature.

Fig. 13.



The mode usually adopted of decomposing light—that of the prism—is well known; and, by similar means, heat may be divided into rays forming a spectrum, which is highly analogous to one of light. A prism of rock-crystal is used for this purpose, instead of one of glass.

A vessel filled with boiling water is the source of heat usually employed. The rays of heat radiated from it are allowed to pass through a small hole in a screen, and, impinging on a prism of rock-salt, they at once undergo refraction, just as light would do by means of the ordinary prism.

The beautiful effects produced by the decomposition of light, are of course visible to the eye; whilst those of heat are not only invisible, but are not perceived by the senses at all. The thermo-multiplier, on being placed in the heat-spectrum, at once evidences the refractive power of the rock-crystal prism, and shows that the heat-giving rays have an unequal refrangibility, just similar to that of the rays of light.

The discovery of this great similarity between heat and light, is of the deepest importance in physical science; and, as we have already stated, it goes to prove the truth of the undulatory theory of those forces. As it completes their analogy in so many instances, the mind is naturally led to infer that heat and light are merely modifications of the same cause.

The polarisation of heat may be effected in a very similar manner to that of light; and the effect takes place when a calorific ray is allowed to pass through a plate of tourmaline or mica. In certain positions of the polariser, heat will pass through, whilst in others the heat is entirely stopped. We shall reserve a fuller description of the result for the section on Polarised Light, because, as that subject has been so widely extended by the researches of modern philosophers, we shall be better able to trace both the facts and analogies of the same properties in caloric.

Heat can not only be refracted by a prism of rock-salt; but if a lens is made of that material, the rays of heat may be collected and focalised, and their effect made evident by receiving them on the thermo-multiplier, although they may be unaccompanied by light. We have here another analogy with light in this singular property. The simplest mode of trying this, is that of placing a lens of rock-salt in front of a vessel containing boiling water, having a screen before it. The end of the battery of the multiplier must then be adjusted to the focal point of the lens. The screen intercepting the rays of heat being removed, the needle of the multiplier will immediately and violently diverge, and thus at once show that the rays have been collected into a focus by the lens.

Experiments of this kind require considerable care and attention on account of their extreme delicacy, and also from the fact that the senses cannot judge of the effects produced, as can be done when light is the force under examination. Much depends on the careful construction of the thermo-multiplier to obtain successful results, and on a proper adjustment of every part of the apparatus employed.

TERRESTRIAL HEAT.

Although the subject of atmospheric temperatures, and the laws which govern their changes, are properly to be considered in detail under the section on Meteorology, it will, however, be convenient that we should enter into the examination of some of the causes and effects of the natural heat of the earth in the present section. The idea has long been held, that the centre of the earth is in a state of intense ignition. The gradual increase of temperature observed in descending deep mines, certainly gives countenance to such an opinion. It is found, that the temperature of a shaft sunk beneath the surface of the ground, increases at the rate of one degree Fahrenheit for a descent of every seventy feet; and, arguing on the assumption that this increase of temperature continues to progress at the same rate, it would follow that, at a depth of ten miles, all substances would be at a red heat, and those melting at a lower temperature than 1000° Fahrenheit would be in a liquid or gaseous condition. The existence of volcanoes, and the boiling fountains or geysers of Iceland, indicates that, at some depth beneath the average surface of the earth, the temperature must be very high.

Some very ingenious speculations have been made as to the cause of the internal heat of the earth. Many have ascribed it to chemical action; and, shortly after the discovery of the metals potassium and sodium, it was suggested that their combustion might, to some extent, account for many of the phenomena observed in volcanic countries. Intense combustion has also been suggested as another cause. Against this idea, however, a difficulty arises, inasmuch as, according to our daily experience, combustion cannot generally occur except in the presence of oxygen. The most feasible mode of explaining the matter seems to be, that at some remote period the earth's surface has been at a much higher temperature than at the present time, but that it has cooled down gradually, by the radiation of heat, into space. It is highly improbable that any definite notion of the cause of this internal heat of the earth will be ever arrived at, because the depth to which we can penetrate in mining and other operations, is very trifling compared with that which would be required to verify speculation, or even to obtain reliable data for calculation.

The application of the laws of the conduction, absorption, and radiation of heat, as applied to the earth's surface, is of the most extended kind. We have already noticed some of the phenomena which arise from the action of those laws. There are, however, two special instances of such in the gulf streams and the trade winds, which deserve further notice, inasmuch as both phenomena depend on the expansive powers of caloric acting on liquids.

There are three parts of the earth's surface where extremes of temperature naturally exist; namely, at the north and south poles, and under the equator. Bearing in mind the laws which we have mentioned in our previous pages, in reference to the expansion, and consequent diminution of density, which all gases undergo when heated, it follows that an ascending current of air should always be found in the equator, which is replaced by the flow of air from the cooler regions of temperate climes, and the still colder polar blast. As the heated air, proceeding at a great altitude, approaches the poles, its temperture is gradually diminished; and, eventually, the hot current is so cooled down, as to become successively the return cold current towards the tropics. It will thus be observed, that by the heat of the sun's rays absorbed, and afterwards radiated by the earth at the tropical regions, an enormous current of air is constantly kept in motion, having a definite direction of its own, and comparatively independent of minor disturbing causes which it may meet with during its progress. There is, however, one cause which modifies the direction of this great calorific current—which is the rotation of the earth on its axis. Now, owing to the levity of the atmosphere, it does not partake so completely of the motion of the earth as it would do if solid. The result is, that the current just spoken of does not take a due north or south direction from either pole, but divides into one passing towards the south-west from the north pole, and another blowing towards the north-west from the south pole. Hence the origin of the trade winds so well known to, and so highly prized by, navigators.

Besides the currents here referred to as the result of the agency of heat, there are an infinity of minor and modifying effects produced by various disturbing causes. The land and sea breeze, before mentioned, owe their origin to partial or local radiation of heat; and the same may be remarked in reference to the mountain storm of wind and rain, where similar causes are always operating on the small scale. The monsoons of India, and the hot winds of the arid Arabian and African deserts, simply result from the effects of the heat absorbed by the sandy plains on the air resting over their surface. A little reflection will at once point out, that the law of the convection of heat by gases, produces results of the utmost importance, and of the most beneficial character throughout nature. Without heat was thus conveyed by means of these expanded air-currents from the tropics, those regions would become a scene of desolation, and of the absence of vegetable and animal life; and were it not that such currents convey the excess of heat from the tropics to colder regions, the latter would lie in one ocean of ice, or in a winter of perpetual frost. The grand arrangement or chain of these laws of heat prevents either catastrophe, and insensibly but surely spreads an airy mantle of fertility and fruitfulness over every part of the surface of our world.

It remains for us to speak of another current which prevails in the waters of the ocean. This is called the gulf stream; and it has a great effect in modifying the annual temperature of the polar regions. An immense body of water, of a temperature of about 84°, proceeds continually from the Gulf of Mexico, in a northerly direction, eventually reaching the shores of Great Britain, where it divides into two streams—one passing northwards, and the other bearing easterly on to the coast of France. The heat of the tropics is thus conveyed towards our own coasts, and hence the prevalence of rain when the wind is in the south-west, because the air is loaded with moisture, which condenses on reaching land. The force of this great current of heated water is such, that plants and fruits, the products of tropical countries, are often cast on the shores of the Western Isles, along the coast of Scotland.

The thermal effect of the gulf stream may be judged of from the fact, that whilst the whole of the American coast, in the same latitude as our own country, is locked in frost during winter, and unbenefited by the genial warmth of this stream, our sea-shores never present the appearance of a mass of ice, through the whole length of the western sea-coast. There is even a less extreme annual range of temperature in the north-west of Scotland, than on the south-east coast of England, although the latter is about 400 miles nearer the equator. The same comparison may be instituted between the climate of Scotland and that of some portions of Denmark, situated in the same latitude.

It has been discovered that there are return currents in the ocean, corresponding to those we referred to as occurring in the atmosphere, and as producing the trade winds. The gulf stream is bounded, and, in fact, rests over such currents; and hence the analogy between it and the trade winds is complete in all respects.

Without trenching on the subjects of physical geography and meteorology, we may state, that there are certain places on the earth's surface which have an equal annual average temperature. This arises from a variety of local and general causes; and the lines drawn on a map expressing the geographical position of such places, are called isothermal lines—a term derived from two Greek words, signifying "equal heat."

The range of temperature in any country varies for the same latitude, according to the altitude of the place of observation above the level of the sea. In our own climate, the limit of perpetual snow is rarely seen, on account of our highest hills being below that point. In the north of Scotland, there is, however, one hill, Ben-Wyvis, on which, as we have been informed, snow may generally be found at all periods of the year. This, perhaps, is partly owing to the winter drifts being so deep as not to allow the high temperature of summer heat to melt them entirely. In more southern climates, the Alps, the Pyrenees, the Andes, and Himalayan range, at all times present a place of continual congelation. In some parts of India and South America, every known climate may be met with, from that of a tropical to one of a polar nature, within a few hours', or, at most, a day or two's journey. Hence the inhabitants of those hot regions of the earth's surface, are enabled to seek and enjoy comparatively temperate climes, and thus to escape the effect of that intense heat which so often proves fatal to European constitutions.

The cause of these temperatures varying with the rise above the sea-level, is easily understood, if we bear in mind the fact, that as a gas expands, its capacity for heat is increased, and that atmospheric rarefaction is always attended by a loss of heat. The reader will remember, that the loss of latent heat in the vacuum of an air-pump is rapidly effected: when ether is thus evaporated from a watch-glass placed in another containing cold water, the latter liquid is thereby easily frozen. Now, at great altitudes, the atmospheric pressure is greatly diminished, and results analogous to those producible in the vacuum of the air-pump are thus presented. Even in a small tract of country, great difference of temperature may be found. These often are owing to rapid evaporation, as in the case of marsh lands, which always maintain a comparatively low temperature. In countries abounding with chalk, such as Kent, the temperature does not vary so rapidly, although in summer-time the heat is highly reflected by chalky soils. Many tracts of land powerfully absorb and radiate heat, and hence their temperature is undergoing incessant change.

We cannot here enter into some most interesting instances of the laws of radiation and absorption, which affect the fertility of the soil. We must not, however, omit to remark, that in these inquiries we continually observe evidences of design, and complete adaptation of means to an end. In winter we have the surface of the earth covered with a mantle of snow, which, by its non-conducting power, prevents the escape of heat, and also prevents radiation. So soon as the snow melts, or the shower of rain falls, the colour of the soil is darkened, and it is thus rendered a better absorber of the genial heat of the sun's rays. As the heating process goes on, the earth dries and becomes of a lighter colour, and is made to radiate less; it is, indeed, thus changed from being a good absorber of heat in its moist state, to be a comparatively bad radiator in its dry condition. By these successive arrangements the soil is enabled to drink in the solar heat, which at the same time so changes the surface as to enable it to store up heat. The seed is thus made to germinate—to grow and to bear fruit—not by a variety of complicated natural causes, but by the application of one simple and unchangeable law.

We might add a vast variety of illustrations which come under our daily experience, in connection with the influences of heat on the vegetable and animal kingdom. As we must confine ourselves, however, in this section to those considerations which strictly belong to Thermotics, we shall reserve our further observations on these and allied matters for our section on Agricultural Chemistry.

HEAT, APPLIED FOR THE PURPOSES OF WARMING AND VENTILATION.

The continual variations of the temperature of the atmosphere in climates situated beyond the tropics, necessitate arrangements for the production of artificial heat; and the different plans adopted for this purpose are but so many accidental or intentional applications of the laws of Thermotics, which we have previously discussed in the earlier pages of this section.

The contrivances of various nations depend very much on the kind of fuel employed as a source of heat. The interior of an Esquimaux snow-hut may be considered as perhaps the rudest, but, at the same time, a very effectual mode of warming, but certainly not of ventilating, a dwelling. Access is generally obtained to the house by means of a long and narrow tunnel, through which the natives creep on the hands and knees. On emerging from the tunnel, a kind of lamp is observed in some part of the snow-house. The fuel employed is common seal oil, which produces plenty of heat and smoke during its combustion. Such lamps serve the double purpose of affording heat and light, and also are employed for that of cooking food. In the arctic regions, wood of course is very scarce; yet nature casts at the feet of these boreal natives the snow, which, as a bad conductor, makes an exceedingly warm house; and the seal, which, like the cocoa-nut of India, serves for food, clothing, fuel, and material for various purposes, to the inhabitants of these inhospitable regions.

Even in the northern parts of our own country, the cooking and warming arrangements of some classes are of the most primitive kind. We have visited many huts in the north Highlands of Scotland, where the only fire-place was a large stone, the chimney a hole in the thatched roof, and the fuel dried sticks, gathered from the neighbouring woods. In many instances, the top of the door of the bothy forms the only means of exit for the smoke of the scanty fire.

The employment of coal as fuel, necessitates that arrangements should be made for an adequate supply of air to support combustion, and also that means should be provided by which the dense and offensive smoke produced may be readily got rid of. Hence the invention of fire-grates and chimneys, having the objects just named in view. It is, however, exceedingly curious to remark, that modern arrangements, such as are employed in our houses both for cooking and heating purposes, are, generally speaking, constructed on principles diametrically opposed to those which sound science would suggest. For instance, the whole of the grate intended to contain the burning coal is made of metal, which, being a good conductor, rapidly abstracts a large portion of heat produced by the combustion of the fuel. The chimney, by means of which the smoke should escape, is often so wide at its mouth as to defeat its object, by drawing up cool air, which thus diminishes the draught; and generally, the grate itself, which is intended to supply warmth to the room, is often "set" so far back, as that a greater proportion of heat escapes up the vent than ever reaches the apartment. It is true that all these objections have been met by the construction of various stoves; but as the use of this kind of heating apparatus rarely finds favour in the majority of cases, our existing arrangement is almost universally the open fire, involving as it does loss of heat, and, therefore, of fuel, besides producing strong draughts of air, which are frequently prejudicial to health.

It is, perhaps, no exaggeration to say, that full one-half of the fuel employed in open fire-places is entirely wasted. In the grates used by the working classes, the loss may even be greater, because such are generally constructed of heavy masses of metal, very different to the more complete contrivances used by their opulent neighbours. Owing to the mass of metal containing the fuel, the heat rapidly passes off on all sides. If, however, the back and sides of the grate were made of some non-conducting material, such as fire-clay, &c., this important cause of waste would be at once removed. Although this can rarely be carried out, still, if plates of clay are so arranged as to completely enclose the burning fuel, a great saving would result. As an illustration of this, we may remark, that a rough fire-place, constructed of bricks, and only having metal in the bars to hold the fuel in front and beneath, will afford more heat for all domestic purposes, at an expenditure of one hundredweight of coal in seven days, than one of the same size, constructed entirely of metal, would give at an expenditure of more than two hundredweight of the same kind of coal, and for the like period. The reason of this is obvious, for the bricks are very imperfect conductors of heat, and, after a time, they become red-hot, and so form, if we may term it, a heat-jacket to the burning fuel, whilst the metal grate has an exactly opposite effect.

Several inventions have been patented and applied for the purpose of diffusing the heat produced from the ordinary fire-grate. Polished reflectors are sometimes placed beneath the fire-bars; and, whilst forming a receptacle for the falling ashes, they at the same time reflect a large amount of heat into the apartment. The top of the fire-place, or the metal arch over and in front of the fire, is often made of polished metal. This, of course, is in direct opposition to the laws of science; because, as this portion of the arrangement is in front of the fire, it can only receive heat by absorption, and throw it off by radiation; and, therefore, it should be of a dark or unpolished surface, which, as we have already explained, forms the best kind of radiator. It is, of course, very difficult to retain that part of the grate forming its sides, above the fire, in a polished state; but just so far as this is managed, so an additional amount of heat is reflected into the room.

It would be impossible for us to enter into detail with respect to the construction of the various kinds of stoves which have been proposed as substitutes for the open fire. In every case, their heating power is obtained at less cost than by means of the ordinary grate, because the whole of the heated surface is placed bodily in the apartment. In most instances, the employment of metal stoves is decidedly prejudicial to health; for not only is the atmosphere dried, and a high temperature induced, but there are certain obscure chemical changes which take place between the atmosphere and the metal (iron), which produce highly injurious effects. These are entirely apart from those results afforded by the products of the combustion of the fuel being allowed to escape into an apartment. Indeed, this very rarely happens in any stove to which a chimney is attached.

With respect to the employment of gas stoves, which have been lately introduced into such general use, it is impossible to speak too strongly in their condemnation. We of course refer to those from which the products of combustion, together with the heated air, are allowed to escape into the apartment. All coal gas contains arsenic, sulphur, ammonia, and other impurities. During the combustion of the gas, these substances are diffused in a gaseous form; and, being inhaled by the lungs, are eventually absorbed into the blood. To speak of the substance most commonly present—arsenic—is sufficient to remind our readers that it is a deadly poison, and one from the use of which we almost instinctively shrink. There is, however, scarcely a room in the kingdom wherein gas is burned, and no means are employed to get rid of its products, that is not more or less a poison propagator; and, by chemical tests, arsenic may easily be detected in its gaseous form, floating in the air. If a small portion of the solid poison is taken into the stomach, we at once seek for remedies with the utmost anxiety; whilst it is much to be feared, that there are thousands of our countrymen, in our warehouses and shops, &c., who are unconsciously and yet daily inhaling its gas, the effects of which, whilst manifested in the decay of health, are really ascribed to other but undue causes.

Similar objections exist to the employment of any source of heat when the products of the combustion are permitted to escape into the apartment, and so to mix with and vitiate the air. The ordinary chauffer in which charcoal is burned, and which is much employed on the continent, has been the cause of numerous fatal accidents. Whenever charcoal undergoes combustion, carbonic acid gas is produced in great quantities. This, if inspired into the lungs, produces speedy death—not perhaps from its poisonous qualities alone, but owing to its containing no free oxygen, which is so essential to animal existence. If a chauffer is used in an apartment wherein abundant means of ventilation do not exist, the carbonic acid gas, or fixed air, as it is sometimes called, at first descends by its weight to the ground, and then gradually accumulates, until, rising in the room to the level of the mouths of persons who may be sleeping, is inhaled into the lungs. It unfortunately produces no painful effects, and some have even described the sensations as really pleasurable; but a heavy sleep is eventually induced, from which the sufferer never again rises alive. It is a matter of great surprise, that, although cases of this kind are continually occurring, the use of these instruments of death largely prevails at the present day. It may, perhaps, be not out of place to name, that a person thus affected with the fumes of carbonic acid gas, may be sometimes restored by removing him immediately into the open air, and by dashing cold water in the face. Generally speaking, the patient should be treated as in cases of drowning, inasmuch as that death occurs in fatal cases from the same cause—asphyxia taking place from the gorging of the lungs with carbonic acid gas. The process lately introduced by Dr. Marshall Hall, for restoring suspended animation (and which has been adopted by the Humane Society of London), is of essential value in such instances.

Having so far noticed the ordinary modes, as adopted in our domestic arrangements, for the purpose of affording heat, we shall next proceed to mention some facts in reference to ventilation; because the two processes—that of producing artificial heat, and of obtaining a supply of pure air—are so intimately connected. Indeed, as we shall presently show, the only means of heating and ventilating the apartments of many modern houses is that of the fire-place, which at best is but a poor and ineffectual contrivance. After having explained some facts in reference to the necessity of ventilation, the products of respiration, &c., we shall treat on the modes of producing warmth by means of steam and hot-water apparatus.

VENTILATION.

We have already stated, that the ventilation of an apartment can only be carried on successfully so long as the laws of expansion by heat are implicitly obeyed. We now proceed to investigate in detail the application of those laws.

Our daily experience teaches us that a constant supply of pure air is essential to our existence; and, in the absence of this, that disease and death will take place. Like many other generally received truths, to which we readily give our assent, this, while believed in abstractedly, is rarely put into full practice; and hence, in most cases, the complete ventilation of our churches, school-rooms, houses, &c., is at present, to a great extent, a desideratum, and often a matter of chance. We have already suggested a very simple experiment,* which will materially assist at arriving at a knowledge of those general laws on which the principles of ventilation depend. We have also observed, that hot air, being light, ascends in a room, and should escape at its upper part; whilst cold air, being denser, remains, till heated, at the lower part, and must also be admitted there. However, at ordinary temperatures, and in a room in which no artificial heat is being produced, a double current of air always exists, provided that openings, such as an open door or window, are there. If any persons are present, then the heat of their bodies and of their expired breath tends to increase the flow of this current, and so to assist the ventilation of the apartment.

In ordinary circumstances, however, the doors and windows of houses are kept closed, for the purpose of

* See *ante*, p. 23—*Experiment* 15.

preventing the escape of heat; and the opening of the fire-grate into the chimney becomes almost the only means by which the foul and heated air can escape. As, however, this opening rarely extends to one-half the height of the apartment, it follows, as a matter of course, that any ventilation which is effected is of the most imperfect nature. The causes of the vitiation of air in any room are so various, and so dependent in many instances on accidental circumstances, as almost to defy enumeration. We may, however, refer to some which are found active in the majority of cases—such as the products of breathing, and of the combustion of gas, oil, and candles.

The constitution of the atmosphere is such as to afford a gas, called oxygen, which, by combining with the charcoal of the food during respiration, is expired in the form of carbonic acid gas on the expiration of the breath. In fact, the process carried on in the lungs of man is exactly identical, in its chemical character, to that which we observe in the combustion of the coal in our furnaces or domestic fire-places. The food we partake of is converted into a peculiar substance, called chyle; and this being absorbed by the vessels of the stomach, becomes converted into blood. The blood thus produced is conveyed, by means of vessels, to the surface of the lungs; and the charcoal it contains is gradually consumed, and its latent heat set free. The charcoal is thus converted into carbonic acid, which is composed of sixteen parts of oxygen to six parts of charcoal, in every twenty-two parts of gas produced. It follows, therefore, that we are continually casting a poison into the air at each expiration of the breath. Besides, having robbed the atmosphere of a portion of its vital part, we also set free at the same time its nitrogen, which forms four-fifths of its bulk, and which is a gas that will not support life. On an average, about twenty pints of air thus vitiated is expired in each minute from the lungs. Exhalations are also continually passing from the skin of the human body, and to an extent far greater than is generally known. Taking these well-ascertained facts into consideration, it is a matter of no surprise that the air of an ordinary-sized room becomes "close" and unpleasant, when even only a few persons may be living in it. Careful chemical tests discover the fact, that our bedrooms invariably contain a larger amount of carbonic acid in the morning than on our retiring to rest; and if three or four per cent. of this gas exists in the air of a room, it is sure to prove harmful, not to say dangerous, to the inhabitants.

Another cause of the vitiated state of the air in confined apartments, is the combustion of various articles employed for the purpose of giving light. Coal gas, animal and vegetable oils, parafin, and tallow, are all composed of the same substances, united in different proportions—namely, hydrogen and charcoal. These, with oxygen, produce, during combustion, carbonic acid and water. It must also be kept in mind, that a minute portion of coal gas, and some of the more volatile parts of oils, always escape unburnt, and hence increase the vitiation of the air beyond that produced by their complete combustion. The annexed table we have calculated from data supplied by Dr. Frankland; and it shows the amount of carbonic acid produced per hour, by quantities of each material sufficient to produce a light equal to that of two sperm candles of six to the pound.

Tallow candles	1.00	cubic foot.
Wax ,,	.83	,,
Sperm oil	.64	,,
Coal gas (London)	.50	,,

From which it appears that tallow candles give off one cubic foot per hour of carbonic acid gas, and ordinary coal gas half a cubic foot per hour, when these are employed to light a room to only a very moderate extent—in fact, affording a light but little better than that produced by burning two "composite" candles. As, however, when gas is used, a much greater light is always maintained, the production of carbonic acid may be reckoned as equal to four times that indicated in the above table, when two burners of the ordinary size are employed in our sitting-rooms.

The products of gas combustion are not only prejudicial to animal life, but are also injurious to furniture, books, &c., on account of the production of sulphuric acid, or oil of vitriol, by the sulphur in the gas uniting with the oxygen of the air. The effect of this acid is found in the complete destruction of the leather of bound books, and of most animal and vegetable substances with which it comes in contact. The colour of many articles, such as curtains and window blinds, is also injured by it; and hence an absence of ventilation is at once a source of both disease and expense.

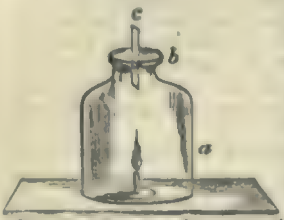
Our remarks have been confined to instances where a want of good ventilation can be chiefly ascribed to the ignorance, and not the want of means of those who suffer from it. When, however, we descend in the social scale, it is scarcely possible to exaggerate the physical and even moral evils which result from inhaling and living in an atmosphere of foul air. Those who have made it their business to visit the houses of the majority of our working classes, have no difficulty in discovering the causes which produce fevers of the typhoid class, and the consequent fearful mortality which ensues. It is by no means an uncommon case to find four or six persons cooking, eating, and sleeping in one room, of very contracted size, from which foul air can scarcely escape, and into which pure air rarely flows, except in the smallest quantity. For the purpose of economising fuel, these apartments are always kept closely shut up. In towns where gas is generally laid on even to the poorest houses, such as Glasgow, Edinburgh, &c., the room is often kept warm by the gaslight, and another source of impurity is thus continually in active operation. The expenditure incurred, and the time necessarily employed in washing, is often a barrier to cleanliness, especially in manufacturing districts, where every member of the family is ordinarily engaged at the factory. Disease of the lungs, phthisis, &c., are natural results of the sudden changes of temperature which are undergone by persons thus living in confined apartments, who are necessarily exposed to the cool air, as they pass to and from the place of their daily avocations. In a moral point of view, the results are equally lamentable. Want of pure air, and a continual breathing of impure air, induce a languor of the system, which in most cases is relieved by spirituous drink. Add to this the contrast of the handsomely fitted and often well-ventilated public-house to the hovel the man has escaped from, and we at once find a solution of the social enigma of drunkenness, poverty, and destitution.

Having stated some of the causes which tend to render the air of an apartment impure, we proceed to consider some of the different plans which may be adopted, or have been proposed, for the purpose of remedying the evil.

The simplest mode of ventilating a sitting or bedroom is that of leaving a space between the bottom of the door and the doorway, for the admission of fresh air, and of having an opening at the top of a room communicating with the outside of the house, by which the foul air may escape. The latter may easily be effected by the removal of a brick, and by covering the opening by means of an iron grid, or a piece of perforated zinc. A still better plan is that of having a large opening in the centre of the ceiling, communicating with the open air. This may be concealed by means of an ornament of any kind. Many objections have been made to admitting air at the lower part of a room, owing to the strong draughts which are thus produced. A very ingenious arrangement has lately been patented, whose principle will easily be understood on trying the following experiment:—

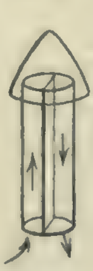
Experiment 30.—Place a glass bell-jar, as represented in Fig. 14, at (*a*), so that its lower end may rest evenly on any flat surface, and thus prevent any air entering. Introduce a lighted candle into it, and, after a short time, the candle will be extinguished for want of air, although the top of the jar (*b*) may be open. Relight and replace the candle, but now divide the neck of the glass jar by inserting into it a card (*c*) so as to form two sections or openings. It will now be found that a current of air enters the vessel on one side of the card, whilst another leaves it on the other side. These currents will be better observed, by holding a little smouldering brown paper near the neck of the vessel, when smoke will be seen to enter, and to leave by the opposite openings. With such an arrangement, the candle may be made to burn any length of time; because a continual supply of cold air is admitted, and the carbonic acid gas is removed.

Fig. 14.



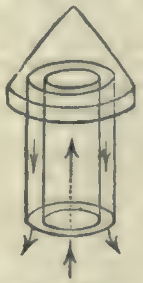
By dividing a pipe, running from any opening in a ceiling, into two parts, in a similar manner as is done by the card in the neck of the glass jar, or by inserting within each other two cylinders, separated by a distance of a few inches, and placing them in an orifice at the top of a room, a system of ventilation may be tolerably carried out. This principle was adopted by Mr. James Kite, about twenty years ago, for the purpose of ventilating ships' cabins. His arrangement consisted of an iron pipe, divided into two parts by means of a slip of metal. Mr. McKinnell, of Glasgow, has improved on this, and has been very successful in his attempts at ventilating many public buildings. The annexed engravings illustrate both of these inventions.

Fig. 15.



Kite's Ventilator.

Fig 16.



McKinnell's Ventilator.

The arrows show the direction of the currents of air.

In this, and similar modes of ventilation, an entire change of the air of the apartment is never produced; because the supply of fresh, and the escape of foul air, are never carried on to sufficient extent for that end. Dilution alone is effected, so that a considerable amount of impurity necessarily remains.

A very ingenious, but complicated plan, was adopted some years ago, by Dr. Reid, in the ventilation of the houses of parliament. Arrangements having been constructed for warming the air when necessary, it was allowed to enter through an immense number of small holes in the floor of the house; the upward draught being produced by a tall ventilator, fixed on the roof. This, whilst highly scientific in plan, was unfortunately not successful in practice. Of course every one present was necessarily in a continuous draught of air; and the result of this, in most instances, is injurious to health, and productive of cold, &c. Few are aware of the difference of being exposed to either an extreme high or low temperature in still air, and in a current of air of the same temperature. In the latter case, rapid evaporation takes place, and consequent cold is produced. Thus, in the Arctic regions, the most intense cold may easily be sustained, provided no breeze is blowing; but the same would be productive of the greatest inconvenience, and possibly of death, during a strong wind. Modifications of Dr. Reid's plan are now often adopted in many large buildings, such as churches, concert-rooms, &c. Air is admitted through openings or grids in the floor; and a number of concealed openings are made in the roof, through which the foul air makes its escape. The burning of gas materially assists this process of ventilation, by causing a continual upward current of hot air. The introduction of "sunlights," which are always placed in the ceilings of rooms, also aids in promoting ventilation.

We may here inquire into the cause of those downward cold draughts which frequently produce so much unpleasantness in churches, &c.; and which, from the ignorance of those in charge of the ventilating arrangements, are often ascribed to wrong causes. In nearly every instance, these downward draughts are chiefly found at the sides of a building; and in the case of churches, they are mostly observed near the walls and windows; and despite all attempts to make the latter air-tight, still these draughts will be felt. Their cause is easily explained. The hot air, rising in the centre of the building, impinges on the roof, and escapes, if suitable openings are made for that purpose. At the same time, the walls and windows being of a lower temperature than the air, cool it, and thus the air descends to the floor of the church, being denser than the central rising volume. If, however, the glass of the windows is covered by means of calico, blinds of any sort, or a thick coat of paint, its conducting power is lessened and the downward draught speedily diminished. Hence the value of double windows, which, by enclosing a body of air between them, prevent the cooling effect which we here speak of.

It is much more difficult to overcome the cooling effect of the walls, because their extent is too great. In many concert-rooms, this difficulty is considerably modified, owing to their being frequently occupied; whereas churches are rarely warmed more than once in a week, and never attain a genial temperature until the daily services are completed, and the requirement has ceased.

A glass window has a power of cooling the warm air of a church, twenty times greater than that of the walls; whilst a double glass window reduces this immense waste of heat to about a fifth of that caused by a single one.

Some years ago, the writer was consulted in reference to this subject, by the trustees of a church in the neighbourhood of London. Having placed a number of thermometers in different parts of the edifice, whilst the usual heating apparatus was in full operation, the cooling effect of the glass windows was at once evidenced by the lower degree of temperature registered beneath them. The officials, however, could not be persuaded that the conducting power of the glass was the cause of the obnoxious draughts, until it was made evident to their senses by filling the building with smoke from brown paper. The currents of air were then easily distinguished, and the cause was at once seen. The remedy applied was thick calico blinds, so arranged as to lie close to the glass, and the evil was thereby greatly lessened.

The employment of steam and hot water for heating purposes, at all times affords a ready means of ventilation. In summer-time, considerable difficulty is experienced in obtaining an upward draught for ventilating purposes, because the external air is often at the same, or even of a higher temperature, than that inside the building. In some instances, large furnaces have been erected on the roof. Through these, the air is drawn by the draught of the burning fuel; and thus an upward current may always be ensured. There is, however, great danger from fire, and also the expense and trouble of carrying up the fuel—objections which strongly militate against the adoption of plans of this kind.

In winter, when hot air is allowed to enter into the lower part of a large room, an ascending current is easily obtained; and thus, if proper means for its escape are furnished, ventilation may easily be effected.

Omitting to mention the use of fixed stoves on a level with the floor of any large room, &c., there are three different means at present adopted for the purpose of warming and ventilation. In each of these, the source of heat is placed beneath the audience, and warm air is admitted from it, and diffused by openings in the floor. Hot air is sometimes produced by allowing external air to pass over iron or brick surfaces enclosing a furnace. This plan is objectionable, because of the extreme dryness of the air thus produced; and also on account of smoke and other volatile products frequently escaping and mixing with the current, to the annoyance of all who have to breathe it.

Hot water, conveyed in iron pipes, is generally adopted, at the present day, as a source of artificial heat in most of our public buildings; and many points of considerable scientific interest are involved in the construction and working of the arrangement. In Mr. Perkins' apparatus, tubes, of an inch in diameter, are formed into a coil, varying in size according to the extent of cubic dimension to be heated. The pipe, rising from the surface of the coil, is extended generally over the flooring of the building, and returns to the coil at its lower part. The coil itself is fixed in a furnace of any kind. The water in the coil, on becoming heated, rises to the upper tube, and traverses the pipes throughout the edifice, so long as its temperature is higher than that of the surrounding air. Having been cooled, the expansion which it had, when heated, is lost, and becoming denser, it returns to the coil, again to pursue the same course on receiving a fresh accession of heat. The philosophy of the process is easily understood, when we bear in mind, that the hot water being light, naturally ascends; on cooling, however, it contracts, and descends to the coil.

The bore of the pipe in Mr. Perkins' arrangement rarely exceeds half an inch. Numerous modifications of this plan have been lately adopted. Cast-iron pipes, of three or four inches in the bore, and peculiarly shaped boilers, are substituted for the small-bore pipes and coil, at the present time; and the use of these arrangements is generally spoken of as effective, and requiring but little attention. By the employment of pipes of large dimensions, such as those just described, the circulation of the hot water is rapidly effected, in a manner which could not be obtained in the smaller kind. Indeed, we have frequently seen the small-pipe coils red-hot, and have observed a temperature of 400° F., at a distance of fifty feet from the furnace, in the pipe conveying the upward current of water. In the boiler and large-pipe arrangement, the temperature rarely exceeds, if it reaches, 212° F.

There is a great advantage in the employment of hot water over that of steam, for heating public buildings—in the freedom from risk of explosion. If a hot-water apparatus should actually burst, not the least danger could possibly arise; the water, in fact, would merely flow out: thus the apparatus may at all times be left to itself, and only requires that the furnace should be supplied with fuel. In the use of steam (to which we shall refer immediately), great care is required that a proper supply of water should be kept up; that the safety-valves should be in proper condition; and other details requiring intelligence and care are involved. The expansion of the water in the hot-water apparatus is always provided for, by inserting in some part of the piping an upright tube, through which the water is first introduced, on erecting the apparatus. A space containing air is left inside this, in which the water gradually rises as it is heated, and expands.

It would be beyond the plan of our work, were we to enter into those practical details involved in applying this apparatus, so far as questions of the size, &c., required for special cases is concerned. This is a matter which must be left to the engineer, and is one which depends on various local and incidental circumstances, which can only be determined as they arise. Our object has been to present the philosophy of warming and ventilation in such a manner, that the principles may be understood and carried into effect by any workman of ordinary intelligence, on the exercise of whose skill and judgment success must of course depend.

STEAM, AND ITS APPLICATIONS.

The process of converting water into steam is so familiar to all, as to require no description. The physical changes which the liquid undergoes are, however, of the highest importance, so far as the laws of its change of state are concerned.

Evaporation takes place at nearly all observed temperatures. If a piece of ice be placed in the receiver of an air-pump, and a watch-glass, filled with strong sulphuric acid, be placed near it, the ice will gradually evaporate, provided that a good vacuum is maintained. Vapour produced at even low temperatures, exerts a pressure on a column of mercury contained in a barometer tube; and as an illustration of this, the following experiment may be tried:—

Experiment 31.—Pour a little ether into a tube of glass, sealed at one end, and about thirty-two inches long. When the tube is completely moistened by the liquid, fill it with mercury. If no vapour existed in the tube, the mercury would stand as high as in the barometer, if the glass tube were inverted into a cistern of mercury, and would act as a barometer at the moment this experiment is tried. But owing to the ether being converted into vapour, and so partially occupying the upper portion of the glass, the mercury will not stand at a height of thirty inches, or thereabouts, but be depressed nearly ten inches below that point, owing to the elasticity of the vapour of the ether. If water be employed, the depression of the mercury will be very slight at low temperatures—perhaps not exceeding half an inch; because it is less volatile than ether. It will be thus perceived, that liquids not only continually evaporate at low temperatures, but that their vapour exerts a pressure on the barometric column proportional to their ready evaporation, or easy conversion into a vaporous state.

It has been already explained, that the atmosphere presses with a force of about fifteen pounds on every square inch of surface at the level of the sea, in ordinary circumstances. The vapour of water presses with an equal force when of a temperature of 212°, the barometer indicating a height of thirty inches of mercury. The annexed table gives the pressure which aqueous vapour exerts at different temperatures, calculated in parts of an atmosphere of fifteen pounds; the column of mercury which the vapour would sustain; and the pressure relative to that of the atmosphere.

Temperature.	Pressure in Atmospheres.	Inches of Mercury supported.	Pressure in Pounds per Square Inch.
60° F.	0.017	0.5	0.25
120	0.120	3.6	1.75
180	0.500	15.0	7.50
212	1.000	30.0	15.00
250	2.000	60.0	30.00
275	3.000	90.0	45.00
290	4.000	120.0	60.00
305	5.000	150.0	75.00
320	6.000	180.0	90.00

It will be thus observed, that the pressure of steam increases in proportion as the temperature is raised; but when the temperature exceeds that of the boiling point of water, the tension of the vapour rises more rapidly, for the same number of degrees, than between lower temperatures.

It is generally reckoned that one cubic inch of water, at ordinary temperatures, is expanded into 1,690 cubic inches, on being converted into steam at a temperature of 212° Fahrenheit; and so long as that temperature is maintained, the steam exerts a mechanical effect equal to fifteen pounds pressure on every square inch of any surface with which it is in contact.

If, however, steam be confined in a vessel—such, for instance, as an ordinary steam boiler—and the production of vapour is carried on continuously, high-pressure steam is produced, which exerts a greater pressure than that afforded in an open vessel. Its density is thus increased, the steam being compressed into a small bulk, in proportion as the pressure augments; and when the steam thus formed exerts a force exceeding that of the atmosphere by fifteen pounds, the vapour has been compressed by the pressure into one-half of the space it would occupy if allowed to escape freely into the open air. The bulk of the vapour is thus inversely as its density. In practice, 100 to 150 pounds per square inch is the maximum pressure used in steam boilers; and these pressures are chiefly confined to the locomotive engines employed on railways.

Besides being employed in the high-pressure engine, steam of a density exceeding that of the atmosphere, has been extensively used in what is called the expansive engine. As the mechanical details of the steam-engine will be fully entered into hereafter, we confine ourselves to stating, that in engines of this class, the steam, after being supplied to the cylinder of the engine, is allowed to expand till the end of the stroke is arrived at; and thus its pressure is gradually diminished, whilst its bulk is as gradually increased. In other forms of this class of engine, two cylinders, of different sizes, are provided, into the smaller of which, the high-pressure steam is first introduced. As soon as the stroke of the piston is completed in this cylinder, the steam is allowed to escape into one of larger size; and there exercising its expansive power, a further mechanical effect is gained; and thus the same *weight* of steam is made to do double duty whilst expanding to its normal bulk at 212° F. This employment of steam is highly economical where water can be obtained for condensing purposes. If very high-pressure steam be employed, as in locomotives, it can be similarly expanded, and is then allowed to escape at a lower pressure in the usual manner, instead of being condensed, as in the low-pressure engines. Great economy in the consumption of fuel is thus effected; and the application of this plan has materially lessened the cost of motive power on railways. In most marine engines, steam of comparatively low pressure is employed, varying from ten to twenty pounds on the square inch, above the atmospheric pressure; and after the steam has exerted its mechanical effect on one side of the piston, it is allowed to escape into the condenser, where, by coming in contact with cold water, it regains a liquid state, by the abstraction of its latent heat.

In an earlier part of this section, we have already directed attention to the doctrine of latent heat; we shall, however, inquire more fully into that law as involved in the production and condensation of steam.

If water be kept boiling in an open vessel, a thermometer immersed in the liquid will not indicate any rise of temperature beyond the boiling point of 212° F. If another thermometer be immersed in the steam which passes off, it will be found to register the same temperature. It therefore follows, that the steam, after attaining a temperature of 212°, must carry off all the caloric which passes into the liquid; and this must pass off in a latent state, because it cannot be appreciated, by any instrument, in a sensible form. The attempt to ascertain the amount of latent heat contained in steam, has received the attention of some of the most able experimenters, who have arrived at various results. It is, however, generally considered, that 1000° of heat, according to the scale of Fahrenheit, are absorbed, and become latent, during the formation of steam. As an illustration of the mode of conducting such investigations, the following experiment is suggested:—

Experiment 32.—Allow steam to pass through a pewter worm contained in a vessel holding a known weight of cold water—say at a temperature of 60° F. As soon as much condensed water, equal to an eighth part of the bulk of the cold water, has been received from the worm of the condenser, ascertain the temperature of the water surrounding the worm. It will have risen to about 188°. Now, as one part of water, in the form of steam, has heated eight parts of water from a temperature of 60° to 188°, or a difference of 128°, it follows that the latent heat of steam is not less than eight times 128°, or 1024°; but as there is a difference between the sensible heat of the water surrounding the condenser, and that of the steam which has passed through it, of 212 — 188, which is equal to 24°, this must be deducted; and hence a carefully conducted experiment gives 1000° as the latent heat of steam at 212° F.

In the condensing steam-engine, cold water is employed for the purpose of absorbing, or taking away the latent heat of the waste steam. As, however, it is necessary that the temperature added to the water should be as little as possible, so as to keep the vacuum perfect, a much larger proportion of water must be employed than we named in Experiment 32, because eight parts were there heated to a temperature of 188°. As, therefore, the temperature of the condenser is never allowed to exceed 110° if possible, about twenty times as much water is employed as the weight of steam which has to be condensed.

It will not be required that we should here enter into the question of economy in the employment of superheated steam, because we shall have to investigate that subject when treating on the steam-engine.

We shall next proceed to speak of the use of steam for heating and warming purposes; and in this we have an interesting instance of the application of the laws of latent heat.

By Experiment 32, we found that steam at 212° will raise the temperature of eight times its weight of water, at ordinary temperatures, by 128°. And here we have a most valuable means of conveying heat to any point we wish, without the necessity of erecting numerous furnaces, or other heating apparatus. Indeed, if steam-pipes are carefully covered with some non-conducting material, such as felt or wood, the steam may be conveyed to very great distances without undergoing condensation. As an instance of this, the whole of the steam-engines at the Exhibition in Hyde Park, in 1851, were worked by steam thus conveyed from boilers in a distant shed; and the same plan is now adopted at the Crystal Palace, at Sydenham. In most of the large bleach and printing-works in the north of England and in Scotland, the whole of the liquids employed are heated by means of steam conveyed into them through pipes, or by steam being admitted into an external vessel, surrounding that which has to be raised in temperature. In many cases, the waste steam passing from a high-pressure engine, is made to raise the temperature of the water supplied to the boiler; and this plan greatly economises the consumption of fuel.

In our remarks on warming and ventilation, we deferred describing the use of steam, from the idea that such would be most conveniently dealt with under this head. For such purposes, an ordinary steam boiler is used, from which iron pipes are carried. These are carefully coated with a non-conductor, until they arrive at the place where the heat of the steam is required. By the radiation of the heat of the steam, at a temperature of 200°, from the iron pipe, a room sixteen feet square by twelve feet high, and of ordinary construction, can be well warmed and ventilated by means of a steam-pipe, twenty feet long and four inches in diameter, or by any other form of metal casing exposing an external surface of twenty square feet. According to this calculation, which was made by Dr. Arnott, it follows, that in rooms or large buildings having the usual amount of window and wall surface, every square foot of steam piping, at the temperature of about 200°, will warm, to an agreeable extent, a space of 150 cubic feet, allowing for imperfect fittings, and for the admission, for the purpose of ventilation, of air, which is also heated during its passage into the apartment. This estimate supposes the external air to be at a temperature below freezing point. Of course, when the external temperature is higher, the same heating surface will have a greater warming effect on the air in the apartment. As we have already explained, the amount of window surface materially affects the success of any heating arrangement.

We have hinted at various objections which apply to the use of steam in churches, theatres, &c.: these, however, do not exist in manufactories where engineers are always employed. Hence, steam is much used in such places as a drying agent, and for various objects which our limited space will not permit us to detail.

TABLES OF THE EFFECTS OF HEAT ON BODIES.

HAVING endeavoured to lay before the reader an exposition of the laws of heat, and their general application, we conclude our section on this subject by supplying various tables, skeletons of which have already appeared in some of the previous pages.

Whilst every endeavour has been made to afford accurate statements for general reference, we must confess, that no branch of science presents so many difficulties when the tabular results of researches are arranged together. Nearly every experimenter differs as to numerical values from those arrived at by his fellow-labourers. And although the science of Heat has occupied the attention of many profound students, still it cannot boast of so great a number as the sister branch of Light;—hence their discrepancies become more glaring. Any person may soon satisfy himself that our remark has foundation in fact, by referring, for instance, to a few tables of the melting point of solids: and it is more than probable, that each work on the subject will present entirely different tabular statements of the required temperature.

Where considerable difference existed, we have supplied the results obtained from various sources, and have mostly omitted the names of their authors for the sake of preventing confusion. We may, however, here state, that we are indebted to the researches of Dalton, Ure, Delaroche, Regnault, Thomson, Daniell, Melloni, and other leading writers on the subject; of whose labours we have freely availed ourselves in constructing the following tables.

Linear Expansion of Solids.

ADDENDA ON RADIANT HEAT.

WHILST the previous pages were passing through the press, some highly interesting observations and experiments, by Dr. Tyndall, F.R.S., of the Royal Institution, have been communicated to the scientific public; a summary of which we append to this section.

Referring the reader to our remarks on Radiant and Terrestrial Heat,* he will find, that we explained, under those heads, the general laws of Radiant Heat; and also alluded to some of their applications in reference to many natural phenomena. We found that various substances had different powers of absorbing and radiating caloric. In another portion of our pages,† we stated, that some gases, liquids, and solids, prevent the passage of calorific rays more than others; and, also, that heat, radiating from any source, undergoes at times both refraction and polarisation. Our remarks also extended to the "diathermancy," or general power of various bodies, in permitting the transmission of calorific rays through their substance at unequal speed.

Dr. Tyndall has extended our knowledge of these various facts, more particularly in reference to the radiating power of the earth, and the absorbing or preventing influence which the atmosphere, resting on its surface, exerts. By numerous experiments on vapours, with respect to the amount of rays of heat of which they permit transmission, we learn from him, that non-luminous rays pass most completely through dry air; whilst some gases and vapours entirely stop their progress, such as olefiant gas and the vapour of ether.

Carbonic acid is found to a limited extent in our atmosphere; and Dr. Tyndall states, that this, in its gaseous form, permits of the rapid transmission of radiant and non-luminous heat, and the consequent cooling of the radiating surface of the earth. An antagonism to this result is found not only in the dense clouds so common in our climate, but also in the action of aqueous vapour, which is always present in the air in temperate climes, and prevents the radiation of non-luminous heat.

Viewing these facts in their practical results, we cannot help being impressed with a deep sense of their value. Under a clear sky, and in dry air, as observed so frequently in the Arctic regions, intense cold continually prevails, and, at the same time, the atmospheric temperature is such as not to allow of the presence of aqueous vapour. As, however, we approach the tropics, the average temperature of the air increases, and with it the amount of aqueous vapour existing in it. Now this, as we have already mentioned, has been pointed out by Dr. Tyndall as acting after the manner of an invisible screen, and preventing the great loss of terrestrial heat which would occur through its absence, in the ordinary process of terrestrial radiation. The general application to Meteorology, of these principles, has yet to be made; but we can easily perceive, that the production or modification of an immense variety of atmospheric phenomena may result from the action of these laws.

Having thus given a general idea of the facts which Dr. Tyndall has developed, we quote from the *Saturday Review*, of March 2nd, 1861, a more detailed account of his experiments, as the best *résumé* to which we have had access; and which will afford our readers considerable information on the subject.

"With his admirable thermo-electric apparatus, Melloni was unable to detect any trace either of the absorption or radiation of heat by air; and we possess no knowledge regarding the action of other gases or of vapours. In the Bakerian lecture, recently delivered before the Royal Society, by Professor Tyndall, the following new results in connexion with this subject were enunciated.

"Oxygen, hydrogen, nitrogen, and air, enclosed in a tube four feet long, absorb respectively about three-tenths per cent. of the calorific rays emanating from a source of 212° Fahrenheit. This is the feeblest action which has been observed. At the other end of the scale stands olefiant gas, which absorbs more than eighty per cent. of the same rays. This gas, which is perfectly transparent to rays of light, is opaque to the rays of obscure heat. Streaming into the atmosphere, it is not seen by the eye; but if a sheaf of calorific rays be caused to cross it, its presence is at once declared by a proper instrument; it intercepts such rays almost as effectually as a screen of cloth drawn across their path. Coal gas acts in a similar manner.

"When a volume of olefiant gas, say one-thirtieth of that necessary to fill it, is sent into an exhausted tube, through which calorific rays are passing, it destroys so many of these rays, that a second equal volume does not produce anything like the same effect. In fact, the rays are not there to be destroyed by the second discharge of gas. But when small volleys of gas are used, the number of rays shot down is exactly proportional to the number of shots. For example—when a measure possessing a capacity of one-fiftieth of a cubic inch was used, five such measures destroyed exactly five times as many rays as a single measure; ten such measures destroyed ten times as much; fifteen such measures destroyed fifteen times as much; but here the rays became sensibly thinned in numbers, so that twenty measures did not produce twenty times the effect of a single measure. As the quantity of gas introduced into the tube augmented, the quantity of rays destroyed deviated more and more from the law of proportionality; until, finally, the addition of a single measure ceased to produce any appreciable effect. At this point, in fact, the vulnerable rays had been practically disposed of. Transparent gases have been hitherto considered as almost perfectly diathermanous; but this opinion can no longer be retained in presence of the fact, that a measure of olefiant gas, one-fiftieth of an inch in volume, diffused through a tube possessing a capacity of 220 cubic inches, and there possessing a tension of only $\frac{1}{11000}$ of an atmosphere, exercises a measurable absorption.

Between atmospheric air and olefiant gas, the other compound gases occupy intermediate positions. In the case of vapours, the most energetic is that of sulphuric ether; the least energetic is that of bisulphide of carbon. Comparing small volumes at equal tensions, the absorptive energy of sulphuric ether is ten times that of olefiant gas, and ten thousand times that of oxygen, hydrogen, nitrogen, or atmospheric air. This vapour, in fact, which, tested by light, is as transparent as the diamond, tested by calorific rays of low intensity, is almost as black as pitch. Between sulphuric ether and bisulphide of carbon, stand chloroform, wood-spirit, benzol, alcohol, the iodides and chlorides of ethyl, methyl, and amyl, and other vapours.

"The influence of the aqueous vapour in the atmosphere may be judged of from the following fact. On a fair November day, the quantity of transparent vapour suspended in the air produced fifteen times the absorption of the true air itself. Philosophers have long speculated on the influence exerted by a diathermanous envelope, like our atmosphere on the climates of a planet. D. Saussure, M. Pouillet, and Mr. Hopkins, have shown the effect of such an envelope in preserving the terrestrial rays from being wasted in space. But, in reality, the atmosphere itself exerts a vanishing influence compared with that of the aqueous vapour it contains. Here we have a constituent, whose changes must produce corresponding alterations of temperature at the surface of the earth. Whether it is competent to account for the variations of climate revealed by geologists, future investigations must decide; but it is a *vera causa* which can never henceforth be overlooked in speculations on the subject.

"It is known that oxygen, obtained from the decomposition of water by an electric current, contains a trace of that singular substance ozone. Such oxygen exerted four times the absorptive energy of the same substance, after it had been passed through the iodide of potassium, and thus freed from its ozone.

"The *radiative* power of gases was examined by causing them to pass over a sphere of heated metal, and to ascend in a column in front of a thermo-electric pile. It was here found that the order of radiation was precisely that of absorption. The theory of heat now universally accepted is, that it is a kind of motion of the atoms of bodies, and *radiant* heat is the propagation of this motion through an ethereal fluid in which all bodies are immersed. A popular exposition of this theory is given by Professor Tyndall, in his *Glaciers of the Alps;* and his recent experiments prove, that every atom, or molecule, which is competent to accept motion from agitated ether—or, in other words, to absorb heat—is competent, in precisely the same degree, to impart motion to still ether, or, in other words, to radiate heat. His experiments have one peculiarity which preceding ones did not possess. They deal with *free* atoms, and thus fix upon them individually the responsibility of the effects observed. In solids and liquids the atoms form joint-stock companies; considerations of cohesion and aggregation come into play, from which the molecules, in a state of gas or vapour, are free. Hence the experiments are calculated to throw light upon the physical characters of the atoms themselves.

"The lecturer pointed out, that the reciprocity of absorption and radiation is a necessary mechanical consequence of the theory of an ether. But the question here arises—'Why is one molecule competent to stop or to generate a calorific flux so much more powerfully than another? What is it, for example, which enables olefiant gas to transcend so enormously in these respects its constituent hydrogen?' To this question the experiments prompt the following reply:—The *elementary* gases which have been examined, all exhibit extremely feeble powers of absorption and radiation as compared with the *compound* ones. Now, in the former case, we have oscillating atoms, but in the latter case oscillating systems of atoms; and if we unite the atomic theory of Dalton with the perfectly independent conception of an ether, it follows that the compound molecule, or group of atoms, which furnishes *points d'appui* to the ethereal fluid, must be capable of accepting and generating motion to a far greater degree than a single atom, which we may figure to our minds as an oscillating sphere. Thus oxygen and hydrogen, which, taken separately or mixed *mechanically*, produce a scarcely sensible effect—when united *chemically* to form oscillating systems, as in aqueous vapour, produce a powerful effect. Thus, also, nitrogen and hydrogen, which, separate or mixed, produce but little action—when *combined* to form ammonia, produce a great action. So, also, nitrogen and oxygen, which, as air, are feeble absorbers and radiators—when *combined*, as in nitrous oxide, are very powerful in both capacities. Comparing small volumes at equal tensions, the action of nitrous oxide is fully 250 times that of air; and there is, perhaps, no fact on record which shows so conclusively that air is a mixture, and not a compound, as this one. Carbonic oxide is about 100 times as powerful as its constituent oxygen; carbonic acid, 150 times as powerful; while olefiant gas, as already stated, is 1,000 times as powerful as its constituent hydrogen. In the case of the hydro-carbon vapours, where the atomic groups attain a higher degree of complexity, the action is still greater than that of olefiant gas. The lecturer also referred to the influence of the rate of atomic oscillation on the amount of heat absorbed. But this subject is difficult to be rendered popular, and is, therefore, omitted here. The discourse concluded by applying considerations similar to the foregoing to the conduction of heat. It was shown how radiation, absorption, and conduction were connected together, and that the phenomena of all of them might be deduced from simple mechanical principles."

CONCLUDING REMARKS.

In the foregoing pages, we have endeavoured to present to the reader, the leading facts and principles involved in that branch of science which treats on heat, as one of the forces of nature. We have found, that whether caloric be considered either as a material substance, or as resulting from the vibrations of an ether, it has certain definite effects on matter. These, whilst characteristic of the action of an individual force, are yet analogous to those of light, as we shall see in our next section.

We preferred to call the attention of the student to caloric, as the first in our arrangement of the undulatory forces; because the principles we have enunciated, call for less mental exertion to comprehend, than those of the forces which we have now to consider. We must, however, presume, that what we have already stated has been fully understood; and that we shall only have to refer incidentally, in future, to those laws we have attempted to unfold. This will be necessary, as tending to save space, time, and useless repetitions.

It may, however, be desirable, that we should point out those special analogies which exist between the laws of heat and light, to which we shall have to give prominence in our future progress. To this end, the student should pay particular attention to the facts connected with the *production*, *conduction*, *radiation*, *absorption*, *reflection*, *refraction*, and *polarisation* of caloric; because we must go over exactly the same ground under the sections of Light and Sound, and show the nature of those phases of force under similar but non-identical circumstances. It is also advisable that a clear knowledge of the doctrine of undulations should have been acquired; and this is more easily arrived at whilst studying the effects of heat, than those of other forces; because such are highly palpable to the senses, and familiar to us in the occurrences of daily life.

In conducting the experiments which we shall adduce in the next section, in support of the principles of optical science, much delicacy of manipulation is frequently required. This, we are aware, is not to be obtained except by long practice. Still, the experiments we have already offered, will serve as an introduction to those which follow; and a frequent repetition of the past, will much assist our progress in the future. Clever experimenters often achieve more success in the study of natural philosophy than deep thinkers; and the latter class often owe the greater part of the success which attends their speculations, to the ready and accurate manipulation of their more expert, but not less valuable, co-workers in the pursuit of scientific research.

There are remote analogies existing between the *latency* of heat and light, so far as their separate or mutual production from matter, by mechanical or other agency, is concerned. The student will find examples of this in our remarks and experiments on the production of heat;* a re-perusal of which may assist him materially in understanding similar phenomena, belonging more exclusively to luminous effects.

Under the head of *double refraction* and the *polarisation* of light, we shall have an opportunity of considerably enlarging on similar effects to which caloric is subject; to which allusion has already been made.† In the course of the work, we shall continually make the remarks in one section to relate to those of the preceding one; conceiving that such a course has the twofold advantage, of impressing the truths of science on the minds of our readers, and also of maintaining that intimate and interesting connection which exists in every department of experimental philosophy.

The subject of Terrestrial Heat is of great interest, in relation to that of Physical Geography and Geology; to each of which we shall hereafter devote an entire section. Dr. Tyndall's discoveries—a *résumé* of which precedes these remarks—may be studied advantageously in connection with it; and if our readers should wish to pursue the subject more fully, we would recommend the perusal of Captain Maury's late work, *The Physical Geography of the Sea;* from which we have made a quotation.‡

Those who may be desirous of turning our remarks on Ventilation, Warming, &c., to practical purposes, will find these subjects ably discussed in works by Dr. Arnott, Mr. Hood, Mr. Tomlinson, and others. We have only attempted to explain general principles, and their immediate application, because our limits would not permit of lengthened details: we, however, hope that the suggestions and observations we have made, will tend to excite the interest of many, who may have both the means and opportunity of applying them to the physical advantage of their less favoured dependents and neighbours. We may especially urge such considerations on individuals connected with establishments wherein large numbers of persons are congregated, such as hospitals, workhouses, schools, &c.

To many, it would seem desirable that we should have included a popular description of the steam-engine; but as we intend, in another part of this work, to devote a section to that interesting subject, any further exposition of its construction, &c., would have been out of place. We shall also have to extend our remarks on the laws of vapour and gases, when treating on Pneumatics. The various forms of land, marine, and locomotive engines, will naturally fall to be considered under the head of Mechanical Philosophy.

Having thus endeavoured to assist the student in carrying out a connected system of self-instruction, we proceed, in the next section, to discuss the doctrines of Optical Science, or that branch of philosophical inquiry in which the nature, laws, and applications of Light are investigated. We shall also deal with the construction and management of Optical Instruments, Photography, and other allied subjects.

SECTION II.

LIGHT, AND ITS APPLICATIONS.

CHAPTER I.

OPTICS, AND OPTICAL INSTRUMENTS.

The phenomena which depend on the agency of light, have been ranged under the branch of science called Optics; and we shall now have to consider this most interesting and fascinating subject.

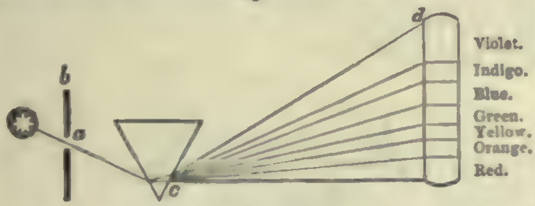
Our Introductory Chapter on the Undulatory Forces, and the remarks which we made thereon in our section on heat, will have, to a considerable extent, prepared the reader for a more enlarged view of their laws and applications in respect to light. We are, indeed, enabled to measure both the number and extent of luminous undulations with great accuracy; and thus shall have the satisfaction of dealing with substantial truth, instead of vague generalisations.

The chief source of light is the sun; and, as we have already remarked, the solar luminous rays are always accompanied by calorific rays, which can, by certain means, be separated from each other. Light, again, like heat, is found in a latent state in all bodies; and by mechanical, electrical, and chemical means, can easily be brought out so as to be perceived by the senses.

The light afforded us by the sun, is called white light; but, by a very simple arrangement, it can be decomposed, and resolved into numerous rays of various colours. For this purpose a prism is employed, which is a piece of glass, of a triangular shape; and on a ray of white light being allowed to pass through it, the component rays are easily separated from each other, and may be received on a sheet of paper, for complete examination.

The annexed figure illustrates the most convenient mode of carrying out this experiment.

Fig. 1.



A ray of sun-light (*a*) is allowed to pass into a darkened room, through a hole in a shutter (*b*), and to impinge on a glass prism (*c*). The light, on emerging from the opposite side of the prism, will be divided into numerous rays, having at least seven different colours; namely, red, orange, yellow, green, blue, indigo, and violet. They are observed in the order in which we have arranged them; the red being always the lowest in the series, and the violet at the upper end. An image of coloured light so formed, is termed a spectrum (*d*); and each of the rays varies, both in respect to its luminous and calorific effect, as we shall perceive in our further experiments.

We have stated, that seven different coloured rays may be thus produced; but, by careful examination, it will be observed, that four of the colours are produced by the overlapping of the other three. Hence, perhaps, in strict truth, we only discover *three* primary colours in a ray of light; namely, blue, yellow, and red. Thus, green is at once formed by combining yellow and blue; the orange ray, by uniting red and yellow; the violet is a combination of red and blue; and the indigo is produced by an intensification of the blue rays.

In explaining the phenomena of the prismatic spectrum, we can happily call in the doctrine of undulations to our aid; and we find that the extreme violet rays are produced by a greater number of undulations taking place at that part of the spectrum, than at the place where the red rays are evident. The subjoined table gives the length of these undulations for each ray of the spectrum.

Colour of Rays.	Length of the Waves in decimal parts of an Inch.	Number of Undulations in an Inch.	Number of Undulations per Second in Billions.
Extreme Red	0.0000266	37640	458
Red	0.0000256	39180	477
Intermediate	0.0000246	40720	495
Orange	0.0000240	41610	506
Intermediate	0.0000235	42510	517
Yellow	0.0000227	44000	535
Intermediate	0.0000219	45600	555
Green	0.0000211	47460	577
Intermediate	0.0000203	49320	600
Blue	0.0000196	51110	622
Intermediate	0.0000189	52910	644
Indigo	0.0000185	54070	658
Intermediate	0.0000181	55240	672
Violet	0.0000174	57490	699
Extreme Violet	0.0000167	59750	727

It will at once be perceived, that a great difference exists in the number of undulations which produce the different coloured rays of the spectrum; and we should here remark, that the luminous rays in which certain chemical phenomena of light are produced, are those of the violet end; whilst those in which the heating effects are most observed, are placed in the red terminal of the spectrum. This is a point of great importance, as we shall observe when we have to enter into the examination of the chemical effects of light, under the head of Photography.

If any coloured substance be placed in any of the prismatic rays, it will immediately assume the colour of that ray; and hence we perceive, that the cause of the colour of bodies is due to the absorption of all the rays of the spectrum but that which they reflect from their surface.

Whilst by means of a prism we can decompose white light, and produce its colours, an experiment may be tried by which the colours can be reunited, and white light at once be reproduced. For this purpose, another prism is to be placed on the one by which light has been decomposed, so that the two may form together a square. The ray of light will pass through without suffering much change. Indeed, the two prisms thus become equal to a solid piece of glass. A slight amount of colour may be visible; and this is owing to the refraction of light occurring when it passes through a dense from a rarer medium—a phenomenon to which we shall have to refer at length in our future pages.

Another mode of illustrating the recomposition of white light, is by painting on a circular card the different prismatic colours, in divisions extending from its centre. If the card be made to rotate rapidly on its axis, a kind of greyish-white colour is produced. This experiment is often employed at the lecture-table, for the purpose of illustrating the composition of white light.

We have already spoken of the speed with which the rays of light traverse space; the experiment, however, which we have just mentioned, is another illustration of the rapidity with which light travels. The first experiments which were made with respect to the speed of light, were conducted by means of a wheel filled with spokes, and which was made to rotate rapidly on its axis. Of course, in ordinary circumstances, all the spokes seem to be lost to sight when the wheel goes rapidly round. If, however, a flash of electric light is made to illuminate them, at the instant the light is produced, each spoke at once becomes visible, because they pass through space in a much longer period of time than does the light which has fallen on them. In passing through a railway tunnel, a red-hot cinder produces a similar optical effect. Previous to the production of its light, the divisions of the sides or bricks of the tunnel would be undistinguishable; but at the instant of the fall of the cinder, every part is immediately observed. Now these effects are due partly to the rapid flight of light, and also to the fact, that the eye cannot appreciate or separate rays of light whose interval of appearance is less than the eighth of a second of time. Hence all the rays passing from the sides of the tunnel seem to be merged together. When, however, only one powerful ray reaches the eye, it at once produces an impression on the retina; and each surface from which it has been reflected becomes instantly visible. This fact may be easily verified by turning round rapidly a piece of red-hot wood, by means of a string, in a dark room. A ring of light will thereby be formed. If, however, an assistant discharges a highly charged leyden jar, so that the light of the spark may fall on the rotating wood, it will at that instant appear stationary, for reasons we have just assigned.

Light, like all radial or central forces, diminishes in its intensity from the source of emission, at a rate equal to the square of the distance. We refer to our remarks on this subject,[*] in which we fully entered into this law, both in reference to heat and light.

Having thus pointed out some general facts respecting the nature of light, we now proceed to investigate some of those laws to which it is subject in its passage from the surface, or through the mass of various bodies, and the changes which it thereby undergoes.

All natural substances may be divided into three classes, so far as the passage of light through them is concerned. Those which prevent the passage of light, or stop the undulations of luminous ether, are called opaque. Some permit freely of its passage, such as glass, crystal, &c.; and these are termed transparent substances. Others only permit the partial transmission of light, as in the case of ground glass, milk, and other substances; and these have accordingly been termed translucent.

When light passes through a body, it undergoes various changes, such as single refraction, double refraction, and polarisation. When a ray of light falls on some substances, such as polished metals, it is reflected; but if it falls at certain angles, it may also be polarised, as we shall more fully point out when we deal with polarised light.

We shall treat on the phenomena of reflection, refraction, and polarisation, under separate heads; because each subject has so many matters of both scientific and general interest attached to it. In our progress, we shall include special applications of the various laws we have to examine, including the use and construction of various optical instruments. We shall also add some remarks on the eye and its structure, which will illustrate the application of many of the laws of the reflection and refraction of light.

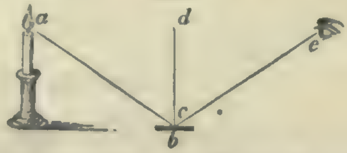
THE REFLECTION OF LIGHT, OR CATOPTRICS.

In our chapter on heat, we stated that that force, as well as light, could be reflected from a polished surface; and this may be of any form; but the shape of the reflective surface has various effects on a ray of either force. The term Catoptrics has been applied to those investigations which are connected with the laws of the reflection of light; and to this subject we now direct attention.

If a ray of light fall on a plane or level surface, such as a piece of glass or polished metal, it is reflected at an angle which has a definite relation to that by which it arrived at the reflecting surface. The angle by which the ray arrives at the reflector, is called the angle of *incidence;* and that by which it leaves the reflecting surface, is termed the angle of *reflection*.

These terms will be better understood by a reference to the annexed diagram.

Fig. 2.

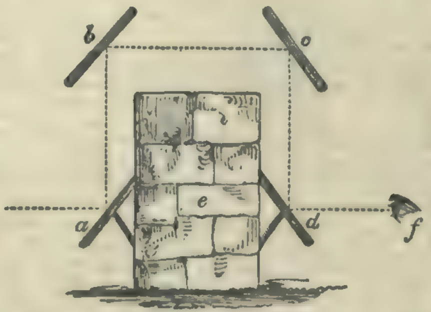


In Fig. 2, *a* being the source of light from which a ray passes to *b* (the reflecting surface), then the angle *c*, *a*, *d*, is called the angle of incidence; *c*, *e*, being the line by which the reflected ray travels to the eye of the observer, then the angle *c*, *e*, *d*, will be the angle of reflection.

Now the law of reflection from plane surfaces is, "that the angle of incidence and the angle of reflection are equal to each other;" so that by being acquainted with either of these angles, the other is known also.

Some interesting applications of this law are often employed in daily life. By means of properly arranged plane reflectors, light may be conveyed to remote places; and thus one source may be made available for a great variety of purposes. Rooms remote from daylight are often illuminated by such means. Coal and other mines have been lighted by reflectors, so arranged, that one large source of light—as, for instance, the electric light—may be made to illuminate distant passages; and thus all danger from the ignition of firedamp is entirely avoided. The whole of one end or length of a street may be observed from an apartment, by a person sitting inside it, if a mirror is placed at an angle of 45° on the outside of the window. A very ingenious contrivance was suggested for employing similar means in warfare. It was proposed to place outside the wall of a battery, an arrangement of mirrors, by which a view of a distant fort might be constantly obtained, without danger of the observer being "picked off" by the enemy's riflemen. This plan is illustrated in our next engraving; and, we believe, was employed during the Crimean war.

Fig. 3.



In Fig. 3, *a*, *b*, *c*, *d*, represent four mirrors, of which *a* receives the view of the fort. This view is successively reflected over the wall (*e*), and observed by the spectator at *f*. Thus, any person placed at *f*, under protection of the wall, will be enabled to observe all that is going on at a distance from him, and yet be unseen by the enemy.

The amount of light which is reflected from any surface, is not equal to that which impinges on it. This is owing to the absorption of some of the rays. We may here remark, that light, like heat, is absorbed in different proportions by various substances. We thus observe very little light reflected from a body of a black colour; and as no metallic body can be perfectly polished, so, from this cause, some of the rays of light are lost before reflection. But even from the most polished surface the same loss occurs; and thus light reflected from water or glass, undergoes considerable diminution in its intensity.

---

[*] See *ante*, p. 14.

We cannot refrain from remarking on the value of this circumstance, when viewed in connection with natural objects. If all bodies reflected light with equal power, the whole face of nature would present a monotonous appearance. Those gradations of tint which form the beauty of the landscape, and the variety of our fields and gardens—the fine effect which a stream of water or river has in the distant prospect, would all be absent. The various reflecting power of different soils, is also of great importance both in a cosmical and agricultural point of view. We here have another instance of one law which is at once universal and beneficent in its operations.

The reflection of light exists on a grand scale in our planetary system. In the centre we have the sun, the source at once of heat and light. Around him are the planets, receiving on, and reflecting from, their surface his borrowed rays. Round the planets we have their satellites, which, like our moon, act as so many enormous reflectors, cheering, during the night season, the side of the planet turned from the sun. Hence, again, the phenomena of eclipses, which occur from the interference, by the eclipsing body, of the rays of solar light, and induce its consequent non-reflection from the eclipsed body.

Two interesting optical toys—the kaleidoscope, invented by Sir David Brewster; and the Debusscope, lately invented by M. Debus—are arranged on the principle of reflection. In the kaleidoscope, plane mirrors are employed, each of which reflect the image of an object placed between them; and thus an infinite variety of beautiful and ever-changing forms may be produced. In the Debusscope, any object placed between the mirrors is multiplied, so as to present a fourfold appearance; and it thus effects a pleasing expansion of any design.

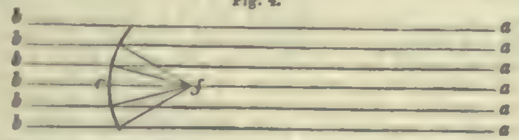
REFLECTION FROM CURVED SURFACES.

We have hitherto referred only to the effects produced by the reflection of light from plane or level surfaces; but we shall now examine the results obtained when rays of light are incident on any polished body of a curved form; and also enter into various applications of the principles we may investigate.

By means of curved reflectors, we are enabled to concentrate the rays of heat and light to a very large extent; or, in other words, we collect rays passing in a straight line on to the mirror; and by its peculiar form, all these are brought together, and joined in one point, called a focus. We may be better understood, if we state, that the object of curved reflectors, is to produce, at one point, the effects of all the rays of light, which had previously only passed side by side, or at an angle with each other.

To illustrate our meaning, we refer to the annexed diagram, Fig. 4, in which rays of light are passing from any source in parallel lines, as from *a*, *a*, *a*, &c., to *b*, *b*, &c.

Fig. 4.



If a curved reflector be placed in any part, say *c*, between *a* and *b*, the rays will not only be stopped in their passage, but will also be diverted from the original straight line in which they had previously travelled, with the exception of the middle one, which coincides with the axis, or line passing through the centre of the mirror at *c*. We shall find, that all the rays thus reflected are joined together at a point (*f*); and this is what is termed the focal point, or focus of a curved reflector.

In practice, this focus can easily be ascertained by holding some burning paper before the mirror, when the junction of the reflected rays will be detected.

It thus follows, that parallel rays of light, passing from a distant source, may, by means of a curved mirror, be brought to a focal point, and their combined effect be concentrated thereon.

If, however, the source of light be placed behind the focus (*f*, Fig. 4), and nearer the mirror, the result will be different. The rays of light will be still reflected, but will pass from the luminous object to the curved surface, and will then diverge in all directions. The student will do well to remember the following epitome of what we have stated, viz.:—When rays of light from a distant source impinge on a curved reflector, they are *converged* to a focus; but when the source of light is placed behind the focus of, and near to, such a reflector, the rays are *diverged* by the reflecting surface.

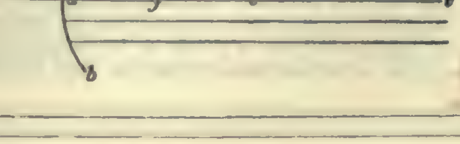
Before we enter into more minute details in reference to curved surfaces, we shall give an illustration of the use of the reflector, which will make plain the statements we have above mentioned. An ordinary reflector, such as is used in carriage-lamps, is an instance of the curved surface we have described. If such a reflector be exposed to the rays of the *sun*, as a distant source of light, it will collect the rays, and bring them to a focal point. If, however, a *candle* be placed behind the focal point, then the rays of light will be reflected in all directions, after reaching the surface of the mirror. These two modes of employing the same mirror, will thus illustrate the difference between the *convergence* and *divergence* of the rays of light; and show that the two reflective results are the reverse of each other in effect. When the rays passing from the reflector are examined beyond the focus, it is found that they have crossed each other; and if an object be placed near the focal point, and observed some distance therefrom, it will be found that an inverted view of it is obtained. We are here confining our attention to a *concave* mirror, or one in which the reflecting surface is "hollowed out," or bent inwards. We shall now examine more minutely into the results obtained in employing this form of reflecting surface, by varying the position of a source of light, or of an object placed at different distances from its focus, together with some of the practical applications which result from the principles at which we shall arrive.

We shall refer, in the following remarks, at first to reflectors of a spherical form; that is, such as would be produced by taking any portion of a globe of glass, or metal in a polished state. The best type of this class of reflector is a common watch-glass, whose *outside* surface has been covered with quicksilver, so as to present an internal or concave reflecting surface. In practice, reflectors of polished metal, of various sizes, are employed; of which, however, we shall speak more fully hereafter.

The law with respect to the reflection of light from plane surfaces, also holds good in reference to curved ones; the angle of incidence being always equal to the angle of reflection. Indeed, a curved surface may be regarded as made up of an infinite number of plane surfaces; and by reflection from each of these planes, to one point, of the rays of light impinging on them, the reflection of curved surfaces is in reality effected.

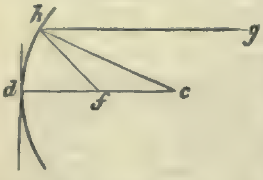
The first case of reflection from a spherical concave mirror which we shall deal with, is that in which the rays of light arrive at its surface in parallel lines. This occurs only from objects at a great distance from the reflector—as the sun, moon, and stars. In Fig. 5, we have an illustration of the effects which result on parallel rays arriving on a concave mirror.

Fig. 5.



Referring to Fig. 5, if *a b* represents a spherical concave reflector, *c* is the centre of concavity, or that point from which, if straight lines are drawn, they shall touch the mirror, and be of equal length; they are, in fact, the radii of the circle, of which the mirror is but a portion: *c d* is the axis of the mirror: *e d* represents a ray of light passing along the axis, and incident on the mirror at *d*. This ray, because passing along the line of the centre of the mirror to *d*, will be reflected back in the same straight line. But if another ray, *g h*, impinges on the mirror at *h*, it will not be reflected back in the same line. The direction which such a ray will be reflected in, will be towards *f*, and will be in the line *h f*. This will be evident if a line be drawn from *h* to *c*; for, as the angle *g h c*, which is the angle of incidence, is equal to the angle *c h f*, which is the angle of reflection, the law of reflection is at once satisfied; and the point *f*, in the line of the centre of concavity, becomes the focus of the mirror, and is situate half-way between the centre of concavity and the centre of the reflector at *d*. This may be better understood to the general reader, if we deal with the subject in the following form. (See Fig. 6, in which we employ the same letters as in the last engraving).

Fig. 6.



Supposing *g h* to be a ray of light touching an exceeding small plane, forming part of the sphere, and that the line *h c* is perpendicular to *h*. Now the angle of incidence, *g h c*, must be equalled by the angle of reflection. To find the latter, draw the line *h f*, so that *f* shall be any point on the straight line *c d*; and in so doing, let the angle *c h f* equal the angle *g h c*. It will be found, that the point *f* is necessarily half-way between *c* and *d*, and, as we before stated, is the focal point of the mirror. This illustration can easily be repeated, by the non-mathematical student, by a pencil on paper; and that plan will assist materially in relieving the difficulty of understanding this portion of the laws of reflection.

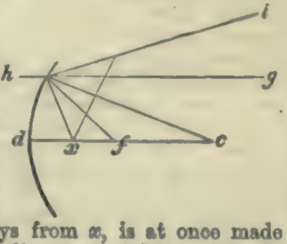
It also follows, that all *parallel* rays impinging on the mirror, except at the point *d*, will necessarily be nearly focalised at *f*; because, with every ray, the circumstances are almost exactly the same. To understand this, suppose the plane *h* to be moved nearer to *d*, and that a ray of light impinges on it in a straight line. In such case, a line perpendicular to its new position must be drawn from it to *c*, the centre of concavity; and as the same course of reasoning must be adopted to explain the results so obtained, the focus of the parallel rays will still be found at *f*.

As an application of the above remarks, we may state, that an image of a star, if its light were thus reflected by a spherical mirror, would be found at *f*.

We may, at this place, urge on those of our readers who may not be accustomed to strict scientific reasoning, that they should not pass any fact or illustration without having thoroughly mastered its details. In every branch of science in which mathematics are employed, it is necessary that succeeding facts should have a relation to those already explained. A chain of argument is thus formed; and if one link be broken, the whole arrangement becomes defective. "Slow and sure" should be the guiding maxim of every tyro in philosophy.

If the source of light be placed in the focus of such a mirror, all its rays would be collected on the surface, and be reflected therefrom in straight lines. This will be at once evident, on considering that by such an arrangement we simply invert the progress of the rays by sending them *from*, instead of *to*, the focus of the mirror. If the source of light were nearer to *d*, the centre of the mirror, than to *f*, its focal point, then the rays would not proceed in parallel lines from the reflecting surface, but would diverge outwards, because the angle of incidence would be greater than those which are produced when the luminous object is placed in the focus; and as the angle of reflection must equal it, that must be greater also. This will be evident on inspecting the following diagram.

Fig. 7.

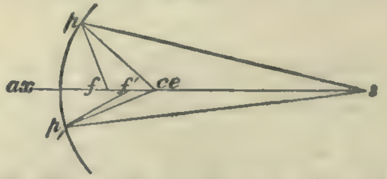


Using the same letters as before, and presuming *x* to represent the new position of the source of light between *f* and *d*, we observe, that if a perpendicular is drawn from *h* to *c*, the angle *x h c* is greater than the angle *c h f*. Now as *x h c*, the angle of incidence, must equal the angle of reflection *c h i*, it follows that the ray of reflected light will diverge as at *h i*; and thus the fact of the divergence of the rays from *x*, is at once made evident by comparing the direction of *h i* with *g h*, the parallel ray.

The foregoing illustration of the properties of rays reflected from a spherical surface, may possibly be difficult to a beginner. We have been compelled to use a circumlocutory description, because we presume that some of our readers will be unacquainted with geometry. To a mathematician, the proposition will appear self-evident; and we trust that, after a little study, others may find the matter easily understood. In every case of reflection, the student should bear in mind the laws of incident and reflecting angles, and, by strictly applying them, many of the problems of optical science will be readily apprehended.

We now proceed to investigate the results which are arrived at when rays of light fall on a spherical mirror from objects at but moderate distances from it, and in lines which are not parallel to each other. To simplify our observations, we shall suppose that a ray of light, from any source, falls on the reflecting surface, as represented in our annexed diagram. (See Fig. 8).

Fig. 8.

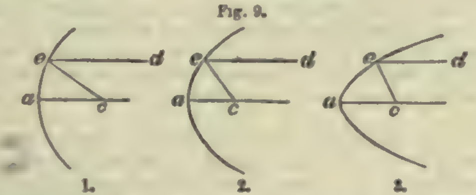


In our illustration (Fig. 5), we presumed that the source of light was at an infinite distance from the mirror, and that all these rays were consequently reflected so as to meet in one point distant from the reflector, and called its focus. In Fig. 8, we suppose the case of the source of light being placed at *s*, and *s ax* to be the axis of the mirror; *ce* the centre of curvature. Let *p* be any plane in the mirror on which a ray *s p* shall fall. The line *p ce* being perpendicular thereto, the angle *p ce f* will be the angle of reflection, and the focal point of this ray will be found at *f*. But suppose another ray of light, *s p′*, to fall on the mirror at *p′*, then *s p′ ce* will be the angle of incidence. Draw a line, *p′ f′*, so as to form an angle equal to *s p′ ce*; then, as the angle *ce p′ f′* = *s p′ ce*, which is the angle of incidence, *ce p′ f′* will be the angle of reflection. But *f′* is not at the same point, in the line *s ax*, as *f*, but is nearer to *ce*. Hence it is evident that all the rays passing from a source of light at *s* will not converge to one point, and of course, therefore, their focus will be removed from that place which would be found between *ce* and *ax* if all the incident rays were parallel. This produces what is termed *aberration*, or what we may call, in plain language, the straying of some of the reflected rays of light from one converging point, and, consequently, the production of several foci instead of one. The optical effect which this produces, we shall more fully inquire into presently.

As the reflectors to which we have referred have been assumed to be portions of a sphere, we generally term the effect of the departure of rays from a common focus as *spherical aberration*. It would take up too much of our space, and we should have to presume a greater amount of mathematical knowledge on the part of some of our readers, were we to enter into an exact analysis of the different curved surfaces which might be employed to overcome this tendency to aberration. There is, however, one curved surface, called the parabola, which, employed as the reflective curve of any mirror, enables us to get rid of aberration, and so to effect the reflection of incident rays in a far more perfect manner. The curve called an ellipse answers a similar purpose. Without, therefore, entering into any mathematical disquisition on the subject, we may state, that, obeying the law of reflection—the angle of incidence and reflection being always equal to each other—rays of light incident on a parabolic or elliptic reflector, will, owing to the properties of these curves, be converged to one focus; and, *vice versâ*, all rays passing from the foci of these curves to the reflecting surface, will be equally reflected therefrom to the other foci of similar curves. The value of this law will be at once seen when we have to refer to the use of mirrors in various optical instruments.

That the non-mathematical student may understand the difference existing between the curvature of a sphere, an ellipse, and a parabola, we annex a diagram illustrating each of these curves. (See Fig. 9).

Fig. 9.



In Fig. 9, No. 1 represents a portion of a sphere; No. 2, of an ellipse; No. 3, of a parabola. In each of these, *a c* is the axis of the curve, and *c* the focus of incident rays. The lines *d e* show the direction of a reflected ray from its source to the focal point.

Having thus endeavoured to explain the laws of reflection of concave curved surfaces, we proceed to examine the effect on a ray of light incident on surfaces of a convex nature. We may state, generally, that exactly opposite results are produced by convex to concave reflectors, the incident rays being always diverged from those of a convex form. Thus, in Fig. 10, we have a portion of a sphere, *a b c*, on which rays of light, *d e*, *f g*, are incident. Instead of converging to a point in front of the mirror, the real focal point would be found at *h*, or that place which would be the focus of rays incident on a curved surface of a concave form, having the same centre of curvature. The ray thus incident will take the direction *c i* and *g i'*, if not in the same line with the axis of the mirror. The ray in the axis of the mirror will be reflected back in the same line as that of incidence, for reasons which we have already frequently explained. The same remarks apply to a parabolic reflector, the internal or concave focus being also that point from which rays incident on its convex surface will be diverged. This is illustrated in Fig. 11, where *f* is the focus of the parabola *a b c*, and *d a* ray of light, which is incident on its convex exterior, and diverged in the direction *a e*.

Fig. 10.

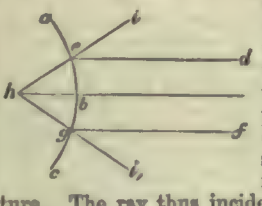


Fig. 11.

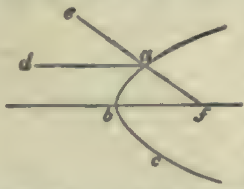


Having thus pointed out some special laws affecting the reflection of light from surfaces of different curved forms, we shall leave their extended application—as in the case of reflecting telescopes—to the subject of Optical Instruments, when the variety of uses to which reflectors are adapted will be fully dealt with. We shall next proceed to examine the phenomena of refraction, which are produced in bodies capable of allowing the passage of light through them; and shall deal with those changes to which a ray is thus subjected.

REFRACTION OF LIGHT, OR DIOPTRICS.

Having examined the results which take place when a ray of light falls on a reflecting surface, we proceed to investigate the phenomena of refraction, or the effects produced when light passes through transparent media of different densities.

If a ray of light pass perpendicularly through any medium of equal or homogeneous character in every part, it will do so in a straight line. If, however, the medium vary in its density, then the ray will be bent out of its straight course; and, to use philosophical terms, we say that it is "refracted." If the ray pass obliquely, the same effect will occur. We shall be better understood if we give instances wherein this refraction takes place. Amongst them are the following.

On looking from the banks of a river at a fish swimming in the water, we see the fish at some distance from its real place, owing to the rays of light passing from its body being bent or refracted from a straight line.

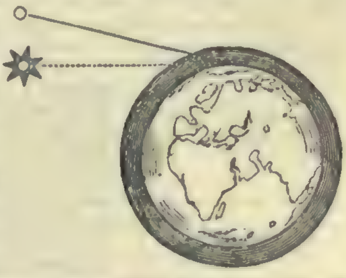
A stick introduced obliquely into a pail of water, appears broken, because the rays of light from that portion in the water, and from that remaining in the air, do not reach the eye at the same angle.

In looking down a long trough of water, the bottom of the trough seems to touch the surface of the liquid at that end furthest from the eye of the spectator. Again, if a coin be placed in a basin, and the observer retreats until he just loses sight of it, the piece of money will reappear on water being poured into the vessel; because, by the refractive power of the liquid, the rays of light are bent upwards, and so reach the eye.

On looking through a piece of window-glass of different thicknesses, all straight lines so observed will appear curved. A similar effect is observed when the eye is placed in a line with the surface of a wall strongly heated by the sun's rays. Objects viewed through the heated air arising from the surface, will appear to assume most fantastic shapes, owing to the refraction of light thus produced.

The refraction of light causes the heavenly bodies to appear, if viewed by the naked eye, much larger when near the horizon than when at the zenith. This effect is often noticed at those seasons of the year when moisture is abundant in the air, or when the atmosphere is heated. The apparent position of the sun is thus altered by refraction; and we therefore observe the disc of that body some time before it has actually risen. This effect is illustrated in the following engraving (Fig. 12), wherein the inner circle represents the earth, and the outer one the atmosphere. The upper line points to the apparent position of the sun before rising; the sun actually being below the horizon, as shown in the second line, although visible to the spectator by the refraction which its rays undergo whilst they pass through the air.

Fig. 12.



Having thus given familiar instances of the effects of the refraction of light, we proceed to investigate the laws in accordance with which its phenomena are manifested.

For this purpose, we annex diagrams which illustrate the progress of a ray of light from a rare to a comparatively dense medium, and *vice versâ*; and at the same time they indicate the refraction or bending of the rays during their progress.

In Fig. 13 we observe the progress of a ray from *c*, at an oblique position to the perpendicular line *a b*. On arriving at the surface of the water, *f g*, the ray does not proceed in the straight line *c d*, but is refracted or bent backward towards *e*; so that when the ray arrives at a certain position in the water, it will be observed at *e*. The student must carefully bear in mind the direction of the ray in our illustration, as *entering* the water.

Fig. 13.

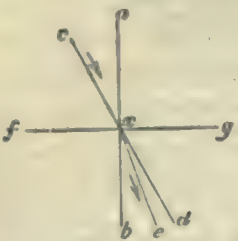


Fig. 14

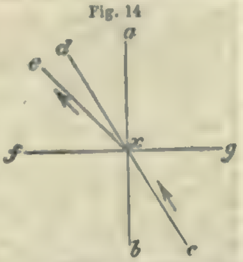
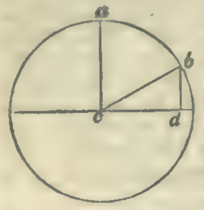


We will now examine the result of a ray passing from any object under the surface of the water; and, for this purpose, refer to Fig. 14, in which we find *c* as the point from which the ray proceeds. Instead of progressing from *c* to *d* in a straight line, we find that the ray is bent or refracted, during its progress, from *c* towards *e*; *a b* still remaining as a line perpendicular to the horizontal surface *f g*.

In Fig. 13, the angle *c x a* is the angle of incidence; and *b x e* the angle of refraction. In Fig. 14 we have the ray of light passing from *c* towards *d*, but refracted towards *e*. Hence *b x c* is the angle of incidence, and *e x a* the angle of refraction. Now if the student will carefully compare the results we here obtain, with those exhibited in the experiment with the coin and a basin of water, he will at once perceive how it is that the ray passing from the coin is refracted or bent back, as we have already mentioned. The case of the fish and the stick in the water are similarly explained; but in these cases we deal with the ray as passing from an object through a dense into a rarer medium.

We next proceed to examine the ratio which exists between the angle of incidence and the angle of refraction; and for this purpose we shall have to call into our aid some of the laws of the mathematical science called Trigonometry. In the annexed diagram we have a circle, in which we have drawn several lines. (See Fig. 15).

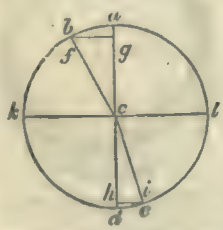
Fig. 15.



The lines *a c* and *c b* are termed radii; and stretch, like the spokes of a wheel, from the centre of the circle to its circumference. The line *b d* is called the sine of the angle *b c d*; and it is to this line that we have to call attention in reference to the index of refraction.

In the annexed diagram we have a circle, in which we have drawn two angles. (See Fig. 16).

Fig. 16.



In this, *a c b* represents the angle of incidence of a ray of light entering a dense medium; and *d c e* the angle of refraction. Now the straight line, *f g*, is the sine of the angle of incidence, and the line *h i* the sine of the angle of refraction; presuming that the line *k l* represents the surface of any refracting medium, such as water, &c. The index of refraction is found by taking the ratio which exists between the two lines or sines *f g* and *h i*; and the ratio varies for different substances, as we shall see by the following table, which gives the index of refraction for several bodies. We shall give a more extended series in an appendix.

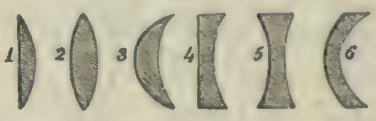
Table of Indices of Refraction.

Refracting Medium.	Index of Refraction.
Vacuum	1.000000
The atmosphere	1.000294
Ice	1.308500
Water	1.336000
Alcohol	1.370000
,,	1.374000
Florence oil	1.485000
Camphor	1.500000
Plate glass	1.514000
Crown ,,	1.526000
,, ,,	1.533000
Brazil pebble	1.532000
Rock crystal	1.547000
,, ,,	1.568000
Amber	1.547000
Flint glass	1.578000
,, ,,	1.601000
Sulphur	2.148000
Phosphorus	2.260000
Diamond	2.439000
,,	2.470000

In looking over the above table of the index of refraction for various bodies, it will be noticed that they differ very much with respect to their bending a ray of light passing through them from its original straight course; and we shall observe that inflammable bodies possess this power to the greatest extent. Sir Isaac Newton noticed this fact, and he guessed that the diamond was composed of some inflammable substance, on account of its possessing so high a refractive power—an opinion which has been verified by chemists, who have shown that that valuable gem is simply a pure form of carbon or charcoal.

Having thus pointed out the nature of refraction, we proceed to explain the principles on which lenses are constructed. Of these there are several kinds, the nature of which will be at once observed, as they are represented in Fig. 17.

Fig. 17.



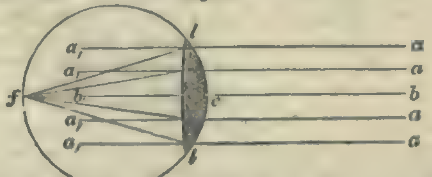
In the above diagram, the various lenses illustrated have the following names:—

No. 1 is a plano-convex lens.
,, 2 ,, double convex lens.
,, 3 ,, meniscus lens.
,, 4 ,, plano-concave lens.
,, 5 ,, double concave lens.
,, 6 ,, concavo-convex lens.

In the plano-convex lens, we observe that one side is a plane surface, whilst the other is convex, and forming part of a sphere. In the double convex lens, both surfaces are curved. The meniscus lens has a similar appearance to a watch-glass, and has its opposite surfaces concave and convex. In the plano-concave, we have one plane, and one inwardly curved surface. In the double concave lens, both surfaces are concave; and in the concavo-convex glass we have two curved surfaces, in some respects like to the meniscus glass, with the exception, however, that, in the concavo-convex, the two curves are about equi-distant in every part.

We now proceed to trace the course of the rays of light passing through the lenses of the different forms above described, commencing with the plano-convex lens, as, perhaps, the simplest for our purpose.

Fig. 18.



Let *a a a a* be a number of parallel rays of light passing through the lens *l l*. Now, it is evident, according to what we have previously stated, that all these rays would continue to pass in a straight line and parallel position, provided that $l\,l$ is a homogeneous substance, or of equal size in every part. But $l\,l$ forms part of a spherical refracting medium, such as glass, &c.; and, as such, the rays passing through it will, with the exception of b', which is in its axis, all fall upon it obliquely, and will therefore be refracted, or bent, from their straight course. Instead, therefore, of continuing on towards a' a', &c., they will incline towards each other, and at last meet in one focus f, which is the focus of the lens under examination. This focal point is found, in the case of the plano-convex lens, to be of a distance, from the centre of the lens $l\,l$, equal to the diameter of the sphere or circle, of which the curved surface of the lens forms part. This will be observed in our diagram, where f is placed at the extremity of the diameter of the circle including the curvature of the lens.

In the double convex lens, the focus is found at the centre of the circle of curvature, and will, therefore, be at only half the length of the diameter of the circle, from the centre of the lens; in other words, the extremity of the radius of the circle, drawn from the glass, will be the focal point of this class of lens. As an illustration of this and the previous rule of finding the foci of these two kinds of lenses, we may add, that presuming the curvature of a *plano-convex* lens to be part of a circle three feet in circumference, then its focal point would be found about twelve inches behind it. If, however, we take the case of a *double convex* lens, we should find the focus six inches behind it, which is about the length of the radius of a circle thirty-six inches in circumference.

As we are confining our attention to the course of parallel rays through lenses, we will next examine the effect thereon when they pass through a double concave lens.

Fig. 19.

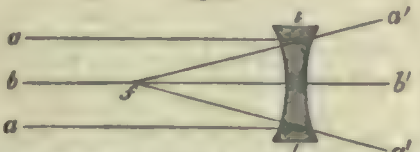


Fig. 19 represents a lens where both surfaces are concave; a b a are three parallel rays of light, incident on one surface of the lens $l\,l$. We shall find that the centre ray b will continue its straight course to b', being in the axis of the lens, and passing through its centre. In the case of the rays a a, we find that they are refracted during their passage, falling as they do on the curved surface of the lens; and on emission on its opposite side, we observe that they diverge, as shown in the lines a' a'. The focus of this lens will be found at f, or at such a point as would be arrived at on the line b, by the refracted rays a' and a', if they were produced backwards through the lens to f, which is the centre of the cavity of the glass.

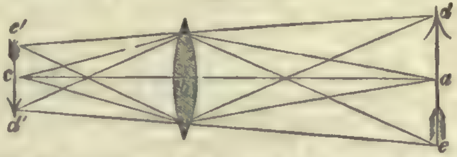
It will be found that f will be distant from the centre of the lens to the extent of the length of the radius of the circle of curvature. If, however, the lens is plano-concave, then, like the plano-convex, its focus will be distant from the centre of the glass to the extent of the diameter of the circle, of which the curve of the lens is a portion.

By following the above rules, the foci of a meniscus and concavo-convex lens may be found: as, however, these are not likely to engage the attention of the reader, we shall not enlarge on the matter.

Having thus examined the effects produced on rays of light passing through lenses of various forms, we shall now refer to other results, which are more especially connected with their practical uses.

If the rays of light passing from an object placed at some distance beyond the focal point of a convex lens, are viewed after their passage through the glass, an inverted image of the object may be seen by placing a piece of ground glass, oiled paper, &c., so as to receive the transmitted rays near the focus, on the opposite side to that of the object. The inversion of the image is caused by the rays crossing each other. This is illustrated in Fig. 20, where a represents the object, b the lens, and c the inverted image.

Fig. 20.



Now, if the rays pass from d in the object a, they will be found refracted as passing obliquely through the lens, and their image will be seen at d', on the screen c; and so with the rays passing from the object at e, their image will appear on the screen c at e', of course inverted.

One of the simplest methods of illustrating this property of convex lenses, is that of allowing the rays of a candle, whose flame is placed beyond the focus of a double convex lens, to pass through the glass on to a sheet of paper placed on the other side. The inverted image of the flame will be at once observed. If a lens, again, is held towards a window, and the rays of light passing from external objects be received on paper or ground-glass, as before mentioned, a complete but inverted representation of them will be seen. On this principle the camera-obscura is constructed, an instrument of which we shall give a full description under the head of Optical Instruments.

On placing a plano or double convex lens between the eye and an object, the latter will present a magnified image, if at about a distance from the lens equal to its focal length: this effect is called the magnifying power of a lens, and varies in proportion to the difference of focal lengths in lenses, when compared with each other. The shorter the distance of the focus from the centre of the lens, the greater will be the magnifying power of the instrument. This effect in convex lenses is owing to our being enabled to view any object at a larger angle, by their assistance, than could be done by the eye alone.

Perhaps the most ready mode of illustrating this law, will be that of referring the student to the apparent diminution of an object as we recede from it. The further we are from any form, the less angle does it subtend to the eye: the nearer we approach to it, the larger this angle of vision becomes; and thus the object appears of greater size. Now the effect of a lens is to collect the rays passing from an object placed at its focal point; and, by refraction, these rays reach the eye, subtending a greater angle on the retina than that existing from the centre of the unassisted eye itself; hence, of course, the image is enlarged. The effect of concave lenses is directly the reverse of this, for they diminish the angle at which an object is seen; and hence the apparent size is also lessened.

We have thus endeavoured to give an explanation of the laws of lenses, and of many phases of single refraction. We shall enlarge on the various uses of lenses under the head of Optical Instruments, in respect of the microscope, telescope, &c. We shall defer the consideration of double refraction to the subject of Polarisation, with which it stands so intimately connected; and shall now attempt to show the application of these laws of lenses, so far as they refer to the structure and use of the eye.

THE EYE AND ITS STRUCTURE.

Fig. 21.

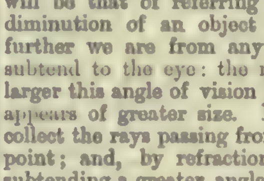


Fig. 22.

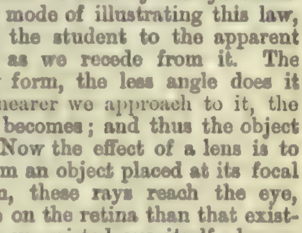


a, the cornea, containing the aqueous humour; b, the pupil; c, the crystalline lens; $e\,f$, the iris; g, chamber of the vitreous humour; h, the optic nerve; $i\,i$, the sclerotica; $k\,k$, the choroides; $l\,l$, the retina.

Presuming that our readers have become familiar with the laws of reflection and refraction, as well as of the construction and use of different kinds of lenses, we now purpose to apply our knowledge in investigating the structure of the eye. We shall also inquire into the different modifications which are found to exist in the eyes of various creatures, and which are essential to the particular conditions in which they exist.

We shall look in vain for any greater instance of perfect adaptation of means to an end, than is found in the construction of the organs of sight. As we proceed in our inquiries, we shall find that every necessity has been provided for; each part is exactly adapted to its purpose; and that simplicity of construction is, after all, the characteristic of this masterpiece of the handiwork of the Deity.

At the head of this section we have introduced two engravings, which give a sectional and general view of the human eye; and we now proceed to describe the uses of each part.

We need scarcely state that one engraving represents the eye as seen from the front. By means of Fig. 22, we shall be able to examine each division, and to ascertain its separate purpose.

We commence with that part which forms the external visual portion of the eye, termed the cornea. This is a transparent horny substance, and encloses what is called the aqueous or watery humour. It forms the first lens in the eye, and refracts rays of light incident on its surface. Referring to Fig. 22, it will be found as marked *a* therein. On the other side of the cornea, the pupil *b* is next observed, which is an aperture through which light passes into the eye from the cornea. A most admirable contrivance exists in front of the pupil—called the iris, *e f*. This is a movable diaphragm, which lets in or closes out light from the eye; and which, by its contraction or expansion, regulates the amount of incident rays in their passage to the retina. The student may easily satisfy himself as to the object of the iris, by observing the eye of the domestic cat during dusk and in full sunshine. When but a dim light exists, the iris will be expanded, and the pupil will appear large. In full daylight, however, the iris is contracted, and the pupil of the eye presents only the appearance of a narrow slit—almost, in fact, shutting out light from the inner portion of the eye.

Beyond the pupil *b*, we next observe the crystalline lens *c*, which has a double convex form. This lens is filled with a fluid of mixed chemical character, and of higher refractive power than that found in the cornea. The centre, *g*, of the eye forms a cell of a nearly circular form, filled with what has been termed the vitreous humour.

At the back of the eye, facing the crystalline lens, we find the retina, so called from its net-like construction. This is at *l l* in our illustration. It is on this membrane that the images of objects, whose rays pass through *a b c*, are depicted. It, in fact, forms a kind of screen, very similar in its use to the ordinary screen employed in the exhibition of dissolving views, &c.

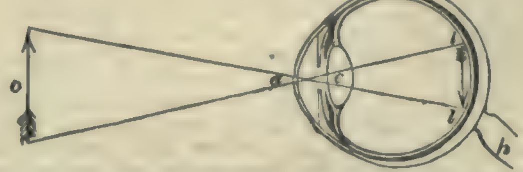
Surrounding, and next to the retina, is the choroid membrane *k k*, which has a black colour, whose office is to absorb the rays of light after they have passed on to the retina. An external coat, the sclerotica, encloses this, and will be observed at *i i*. This extends to the cornea, and forms what is called the "white of the eye."

At the back of the ball of the eye, we observe a projection extending from it. This is called the optic nerve, *h*, and, by its action, the image painted on the retina becomes perceived by the mind. In fact, it forms the connecting link between mind and matter, and is the channel of nervous sensation between the eye and the brain.

The reader will thus perceive that there are three different cells, each filled with fluids. These differ in their refractive power; the index of that of the cornea, *a*, being 1.337; that of the crystalline lens, *c*, 1.384; and of the vitreous or centre of the ball, *g*, 1.339.

Having thus described each portion of the eye, we proceed to examine the course of a ray of light from an object incident on the cornea.

Fig. 23.



In Fig. 23, retaining the same letters as those we employed in describing the eye in Fig. 22, we observe the rays of an object, *o*, proceeding to the cornea, *a*, and passing to the crystalline lens, *c*. Here they undergo refraction, just as they would if passing through a double convex lens made of glass; and eventually we find that an image is painted on the retina, as seen at *l l*. It may be more satisfactory to the student to try an experiment with the eye of an ox. For this purpose he should remove the external coatings of the eye, including the retina; and by placing a piece of ground-glass against the cell, which contains the vitreous humour, in the same position that the retina had previously occupied, he will at once perceive an inverted image of any object whose rays have passed through the cornea, the crystalline lens, and the vitreous cell.

The reader will at once perceive that the image painted on the retina is inverted, and will, doubtless, inquire how it is that we see all objects in an apparently vertical position? The answer hitherto given to this question is at least unsatisfactory. It is generally stated, that the distinctions between top and bottom, and such expressions, are merely the results of habitual experience; or, in other terms, we express ourselves in such a manner as accords with the impression of our minds. "Seeing properly," therefore, becomes a mere question of education, just as the sense of touch, &c., may be similarly explained. This, however, is a subject on which it is useless to spend space and time in discussing, and any attempt at analogical illustration would by no means clear away the difficulty of the question.

One of the most astonishing capabilities of the eye, is its power of adapting itself to view objects at different distances. It is evident that some change must take place in the shape of the lens of the eye, when rays of greatly different positions as to distance pass through it. The mode of action may be twofold. The crystalline lens may be enabled to alter its shape, and therefore its convexity, of its own accord, or the entire ball of the eye may perform the same operation by the contraction of the muscles surrounding it. Each view has had its advocates and its opponents. It has been properly remarked, that the crystalline lens has no muscular structure sufficient for the purpose; and, on the other hand, that the contraction of the muscles surrounding the eyeball would, if exerted sufficiently, tend to disorganise the whole structure of the organ. This subject is one of great difficulty, and not to be easily decided. We are at present much in the same position on the question, as the man who, although his blindness had been removed, could not explain the chain of causes existing between the fiat of his Great Physician and its result. We may explain our position safely and correctly by quoting his words, as one of the most logical and satisfactory of conclusions: "One thing I know, that whereas I was blind, now I see;" and thus we likewise must be content with a simple statement of facts.

Having confined our attention to the structure, &c., common to both eyes, we have now to speak of another subject, which also presents some difficulty; namely, how is it that we see singly by means of two eyes? The readiest answer to this is, that if any image be presented to each eye, at such a distance from either that the two images overlap or join each other, then the object will be viewed singly. The student will understand what we mean by trying a very simple experiment. Place the fore-finger between the eyes, parallel to the nose, and not exceeding an inch in distance therefrom—the finger will thus be seen double. Now, move the finger gradually from the face, and observe the effect produced. It will be seen that, as the finger retrogrades, the two images, previously separated, will gradually merge into one, so that, at a distance of six inches from the nose, only one image will be observed. In fact, a gradual junction of the two images is thus effected.

Again, bring the eyeballs into such a position that all distant objects appear double—just, in fact, so that the axes of both eyes shall be directed to a point close to the line parallel with the nose. If the finger be now held at a distance of two feet from the eyes, it will appear double: if, however, it be gradually brought so as nearly to touch the nose, its two images will gradually coalesce, and one image will be formed in the same place as that in which two images were observed in our last experiment. In this case we have brought, by the process of "squinting" (as it is sometimes termed), the two axes or lines of vision of the eye, so as to join each other at a distance much less than that adopted in ordinary sight, and have so produced an inversion of effect. In either case, however, the cause was the same; namely, the overlapping of the two images impressed on the retina, but at different distances from a point situated midway between the two eyes.

We may here explain two instances of defective sight, which we observe many persons to be troubled with. They are those of long and short sight. In aged persons, we find that the shape of the cornea has become altered, and less convex than is the case in a healthy state of the organ. The remedy for this is very simple; for what is deficient in the eye is easily supplied by means of convex lenses;—hence the general use of spectacles by old persons and others, in whom the cornea is deficient in convexity. This state of the eye permits a person to see well enough any distant object, because the rays proceeding thence are comparatively parallel to those emanating from an object nearer to the eye.

In the case of "short-sighted" persons, the cornea is far more convex than in ordinary cases. The use of concave glasses is therefore essential to such, and they at once supply the requisite remedy.

We shall speak more fully on this subject when we treat on optical instruments; and shall defer the consideration of some peculiarities of vision, in reference to colour, to our section on the phenomena of colour.

In many of the mammalia, the uses of the eye being, to some extent, similar to those of the human subject, its construction is mostly similar. Considerable susceptibility to the action of light, in some animals, is generally attended by a greater irritability of the iris; and thus we find those creatures which have their type in the common cat, possess better power of sight during dusk than at other times. As we have already remarked, the pupil of the eye contracts during strong daylight, and expands as the light becomes less intense. The same adaptation of organism to special circumstances is found in the owl, &c., amongst birds.

The eye of the fish is peculiarly adapted to the condition of its existence, and may be taken as a kind of antitype of the organs of sight of insects. The fish naturally exists in a liquid whose refractive power is scarcely different to that of its organs of sight. In the insect we find a most remarkable construction of the eye; and of this class we may refer to the eyes of the bee and the fly, which are formed of a multitude of lenses. In general, we may state, that the shape of the cornea is made to depend on the circumstances in which the creature has to maintain its existence. Thus, fishes have the cornea flat, and the crystalline lens more spherical; whilst the cornea of the eye of the bird has greater convexity, and the crystalline lens is less convex than that of other creatures.

There are some interesting facts relating to the construction of the human eye as indicating design, which we must not omit to place prominently before our readers. Our remarks on aberration* will prepare us to expect that special provision has been made to prevent the consequences of that defect which causes so much loss and diffusion of light in spherical lenses. In the human eye, the curvature of the cornea and crystalline lens is such as entirely to prevent any chance of such a defect existing; they, in fact, being elliptic, and hence exactly of that form as would be required for a non-aberrant lens. The voluntary motion of the iris regulates the amount of light which can enter the eye. The change of the convexity of the cornea provides for a distant or close view of any object at pleasure. The mobility of the eyeball enables us to instantly change the direction of sight. The refractive powers of the humours of the eye are exactly such as are required for the medium in which we live. External to the eye, we have the protection of the eyelashes, which serve as a screen to preserve the organ from the intrusion of foreign matter on its surface. The prevalent colour of both the air and the surface of the landscape, is just that which agrees with the optical necessities of sight. Whilst the ear cannot be closed to external sound, the eye, which is an infinitely more delicate organ, can be shut off from external impression, by the motion of the eyelids, at any moment, and thus injury to its delicate organisation may be almost entirely prevented. In no point of view, therefore, is perfection and completeness more evident than in the arrangement of the different parts of the eye of man.

It may also be remarked, that the eye is less subject to disease, in general, than any other organ of the human system. Despite its constant use, and apparent exposure to external injury, we find, on an average of instances, that it stands the wear and tear of life to an astonishing extent. The changes of the healthy organ are very gradual; and thus it is only towards the close of life, when all the faculties and senses become dulled by age, that the power of sight becomes seriously affected. Even then, science gives to a "green old age" a "second sight"—the very disease, indeed, suggesting its own remedy. Whilst, during life, the eye is the exponent of the sentiments of the mind—alternately beaming with pleasure or dimmed with pain—it generally maintains vitality to the closing scene, and, by its last glance, indicates the farewell of its possessor to the changes and shadows of earthly existence.

THE PHENOMENA OF COLOUR.

Having investigated the principal laws of the reflection and refraction of light, we shall now enter on the consideration of a most interesting branch of optical science; namely, the cause of colour.

We have already stated that white light is composed of certain rays which have been called primary colours; and we shall presume that the reader has become acquainted with these, by examining the spectrum produced from a ray of light refracted by means of a glass prism. We, however, must remark, that the characteristics of a spectrum vary according to the substances employed as a prism; and by having a triangular vessel arranged so that it can be filled with liquids of various refracting powers, the student will soon discover, by its use, the results to which we here refer.

The chief effect produced by employing various substances in place of glass as a prism, is, that some have a greater dispersive power over the rays of light passing through them than others. Thus, a prism of flint-glass increases the extent of the image of the coloured rays much beyond that produced by one of crown-glass. And the same may be stated of many other substances. Some have the power of extending certain of the spectral rays in preference to others, and of thus having a special action on one or other end of the prismatic image.

We have already stated that the different rays of the spectrum may be divided into three kinds—the luminous, the calorific, and those having a chemical action on certain bodies. The chief of the luminous rays are found in the yellow; the greatest heating effect in the red; and the chemical power exists entirely in or beyond the blue band. By placing a thermometer in the various bands of colour, the student will be enabled at once to perceive how much more heat is to be found in the red than in the blue rays; and if a piece of note-paper be well soaked in a solution of common salt, and, when dry, moistened with a solution of nitrate of silver, it will be a test of the power of the chemical rays. If placed in the blue or violet band, it will be speedily darkened, owing to the chemical action of the violet ray on the salt of silver on its surface. In the red ray it will scarcely undergo any perceptible change.

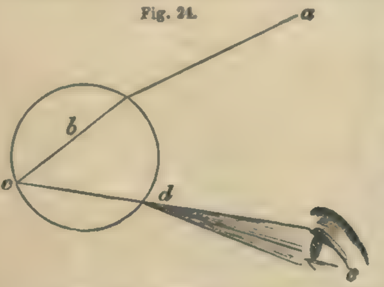
---

* See *ante*, p. 44.

The most convenient mode of conducting this instructive experiment, is by stretching a piece of paper, prepared as above, along the entire length of the spectrum, so that all the rays from the red to the extreme violet may fall on it. The paper will be darkened just in proportion to the energy of the blue rays, and unaffected in the yellow and red. Both the calorific and chemical rays extend, however, beyond the visible spectrum, and are more energetic than at the point where light ceases to be perceived: of this, however, we shall speak fully hereafter.

The well-known phenomenon of the rainbow is easily explained, on principles similar to those involved in the production of the prismatic spectrum. Indeed, each drop of rain, by refracting the rays of light incident on it, acts as a prism, and produces the coloured image which is impressed on the retina of the eye. The reason of this will be better understood if we examine the effect produced on a ray of sunlight falling on the rain-drops, as illustrated in the annexed engraving. (Fig. 24.)

Fig. 24.



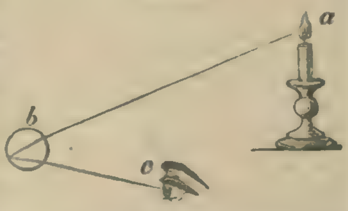
We will suppose *a* to be a ray of light falling on the rain-drop *b*, the sun being behind the spectator, and the rain-drop facing him, and at a certain angle with the sun and his eye. On entering the drop, the ray is, of course, immediately refracted, passing as it does, in an oblique direction, from a rare into a dense medium. It will arrive at some point in the drop (say *c*), and a portion of it will be transmitted. Another part, however, will be reflected to *d*; and as it leaves the drop the emerging ray will be divided, and its colours will be evident to the spectator at *e*. It will be at once perceived, therefore, that the rain-drop acts precisely as a prism; and in like manner the different coloured rays reach the eye, in the same order as in the prismatic spectrum; the blue rays being observed at the top, and the red rays at the lower part of the rainbow. Of course, what is true of one drop is equally applicable to all, and their great number combines to produce the unparalleled splendour which the "bow in the heavens" presents to the eye of the admiring observer. With respect to the order in which the colours of the rainbow are seen, we must add, that each coloured ray has a special angle of its own; and as these emerge from each drop of water, they successively reach the eye in the order of the least refrangible or red rays in an inferior, and the more refrangible or blue rays in the superior, position. The student will thus perceive a beautiful illustration of all the laws of reflection and refraction to which we have already alluded in the phenomena of the bow, whether produced by the shower of rain, or by any means where water, in a minute state of division, can be placed in the proper angle of light incident on it.

A most beautiful effect is produced by casting the prismatic spectrum on steam rising from hot water, which affords an appearance much resembling a rainbow. Artificial means can easily be employed for producing the appearances of a "bow," by casting light on water issuing under pressure from an orifice, so as to form spray. In a similar manner a "rainbow" may often be observed over a waterfall, and at the bows of a steamer, or near the paddle-wheels when they are in motion, because the water thus cast up is in a favourable state of minute division for affording the bow-like appearance on a small scale.

The rich variety of colours observed during sunrise and sunset, is equally due to the refraction of light produced by the moisture held in the state of vapour in the atmosphere. Generally speaking, the more dense the state of the vapour or clouds, the more inclined to a red appearance is the effect produced; and by a gradation in the amount of moisture present, every variety of tint is thus produced. Hence, we invariably find, that the colour of the clouds towards sunset is of a deep red tint, because the refraction is greater at the horizon than at the zenith, whether in the presence or absence of cloud. There are many other appearances of coloured light observed round the sun and moon during cloudy weather; and all these are easily explained, on the principle of the refraction of light, by its passage through, or reflection from, globules of aqueous vapour.

If the student place a round and solid ball of glass so that the light of a candle may impinge on it in a manner similar to that observed when the sun produces the rainbow, he may easily observe all the effects of coloured light, produced by the rays from the candle being refracted by the glass.

Fig. 25.



The best mode of carrying out this simple experiment, is that represented in Fig. 25, where *a* represents the flame of a candle, *b* a solid globe of glass an inch in diameter, and *c* the position of the eye, some way between the glass and the candle, so that the latter may be behind the spectator. The ray of light will pass to the back of the glass globe, and, having been refracted, the observer, if placed at angles varying from 40° to 50° with a straight line drawn from the glass globe, between the eye and the candle, will perceive the coloured rays of light in their natural order of succession. As the head is moved towards the light, the blue rays will be perceived as reflected from the glass; but, on gently moving the eye from the candle, all the prismatic colours will gradually present themselves. An easily understood experiment will be thus afforded, giving a good insight into the laws which govern the production of coloured light in atmospheric phenomena. Even a glance at an ordinary chandelier pendant, will give the same effects, and is a still more common illustration of the points we have mentioned.

On similar causes to those we have here explained, the beautiful play of colours seen when a brilliant is viewed by reflected light, depend. The light is refracted by entering the substance of the diamond, and, on subsequent reflection, the coloured rays are perceived by the eye.

The colour of all bodies is simply caused by their absorbing every ray of the prismatic spectrum, except that which reaches the eye. Thus, if we look at a red article, we state, as the reason of its colour, that all the rays of every other coloured light are absorbed by the material, that of red only being reflected from its surface. Of course, the same argument is applied in reference to all colours which can be perceived. We must here refer to those admirable researches instituted by Sir Isaac Newton, which have thrown great light on this most interesting subject.

Every one must have noticed, that when oil, tar, and other liquids are dropped on the surface of water, a variety of beautiful colours is produced. Sir Isaac Newton, by forming thin plates of air through pressing two glass surfaces together, was enabled to even measure the thickness of these plates for each colour afforded. As these results are of great importance, we give directions, by following which the student may easily reproduce them at his convenience.

Experiment 1.—Place a glass lens, of a focal length of ten or twelve feet, on a flat plate of glass, and press the two surfaces together. It will be observed, that if great pressure be employed, a small dark spot will be produced at the point where the two surfaces are nearest each other; and round this point a series of concentric circles will be formed, each being of a definite colour, and varying from violet to red.

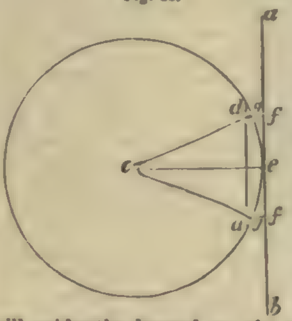
Experiment 2.—Boil some water in a Florence flask, or other glass vessel, and throw into it a pea of Castille soap. When steam issues from the neck of the vessel, and all the air has been expelled, cork the flask so that it shall be air-tight. On shaking up its contents, thin films will be formed, presenting a similar set of appearances to those named in the last experiment.

Now, the production of these colours is due to the fact, that the plate of air or film of the soap-bubble is of exactly the thickness required to produce the colours observed. If the plate be exceedingly thin, then no light will be reflected, and the spot will be black. If somewhat thicker, then violet light will be perceived; and so on until the plate becomes of greater substance, when red light will be reflected from the surface, and so reach the eye.

If, however, the observer look *through*, instead of *at*, the plate of glass, he will see what are called the *complementary* colours, which, combined with the colour observed, would produce white light. These experiments enable us to tell the thickness of a plate of air; and, therefore, the length of an undulation of light of any colour; for we have only to learn the distance between the lens and the flat glass at any point where we notice a colour whose undulation we wish to study, when the length of the undulation is of course obtained. This is easily done; for, knowing the size of the circle of which the lens forms part, we can at once learn the length of any arc of that circle, and, taking the length of the tangent of that arc in which we observe the undulation existing, we can obtain the thickness of air between the tangent and the curve of the circle.

This will be easily understood by referring to Fig. 26, in which *a b* represents a flat glass plate, resting against a lens *d d*, which forms part of a sphere whose centre is *c*. Let *f f* be the extremities of a ring of coloured light distant from *e*, which is a point where we will suppose a black spot, or place where no light is reflected; *e f* is, of course, the tangent of the angle *f c e*. Now *f g*, the thickness of the plate of air, will evidently depend on the angle which *f* forms with the radius of the circle *c e*. The length of *c e*, *c g*, being easily obtained by ordinary measurement, *f g* is, of course, as easily found. It follows, that the smaller the angle existing with respect to the centre of the circle *c*, the thinner will be the plate of air between the lens and the glass plate *a b*. As the measurement of all intermediate distances involves only the ordinary rules of mathematics, the student will at once perceive that we can thus calculate the thickness of any coloured plate, and, therefore, infer the length of an undulation of any ray of light under examination.

Fig. 26.



We have thus endeavoured to explain how we are enabled to measure the thickness and length of these plates of air; and having once ascertained the facts of the case, their general application is easily arrived at. Thus, if we observe that a soap or oil film presents the same colour as that which we find at any part between the lens and the glass plate, we at once infer that the thickness of each is equal. There is, however, a limitation of the law, which we must carefully bear in mind. It is, that the thickness of plates of different materials reflecting the same coloured light, is inversely as the ratio of their index of refraction. Hence plates of various transparent media, such as air, water, glass, oil of cassia, &c., are of different thicknesses when producing similar optical coloured effects.

We append a rough illustration of the position of the colours as observed between the lens and the plate, and a table of the thickness of the coloured plates; but must here state, that for the sake of simplicity, we have confined the attention of the reader to the production of only one order of rings. There are, however, several of these produced. The relative thicknesses and positions of the first order are pointed out below, and represented in the annexed engraving. In Fig. 27, *a* represents the lens placed on the glass plate *b*, and *c* is the interval existing between the two. In the annexed table, the numbers in the figure above indicate the position of the reflected colours placed before them; and the thicknesses of these are also given for the series of rings, commencing from the nearest or central point of contact.

Fig. 27.

	Colour.	Thickness in parts of an inch.
No. 1	Black	.000005
„ 2	Blue	.000024
„ 3	White	.000052
„ 4	Yellow	.000071
„ 5	Red	.000090

The above being the reflected colours, it follows that their complementaries will be seen by transmitted light.

The means of measuring the length of an undulation being obtained, we can next proceed to calculate their speed. We have already given a table of these;[*] to which we now refer, whilst we enter into their calculation in detail.

Having found the length, in parts of an inch, of an undulation, and knowing by the eclipses of Jupiter's satellites, that light travels at the rate of 192,000 miles per second, in round numbers—it follows that there will be as many undulations of any coloured light, in a second of time, as there are parts of an inch equal to the length of one wave in a distance of 192,000 miles, which the ray has travelled during one second. (See also p. 168.)

We have previously mentioned,[†] that an extreme red ray has a length of undulation of 0.0000266 of an inch; and if we divide 12165120000, the number of inches in 192,000 miles, by this length of one undulation, we obtain the result of about 458 billions of vibrations in one second of time, as producing the extreme red ray of the prismatic spectrum. The same result is afforded by multiplying the number of undulations per inch by the number of inches in 192,000 miles. Thus:—37640, the number of undulations per inch for the red ray, multiplied by 12165120000, the number of inches in 192,000 miles, gives 457,898,116,800,000 as the number of undulations per second of a ray of red light.

We have been particular in detailing the mode employed in calculating this result, because we are not aware of any work in which the entire process has yet been mentioned. The student will not fail to be impressed with the astonishing minuteness and rapidity of the undulations which produce the magnificent effects of colour; and perhaps we can scarcely point out any instance in the range of science, in which so great a number of proximate causes is constantly required to produce one well-known, and therefore, perhaps, often unappreciated result.

We need scarcely add that the undulations of each of the other coloured rays are calculated in a similar manner for every band in the spectrum. As a matter of practice, and to impress the laws which we have been here illustrating, the student will do well to continue these calculations of the speed of each undulation, taking the table before mentioned as a guide, and as affording the requisite data.

---

[*] See *ante*, p. 41.

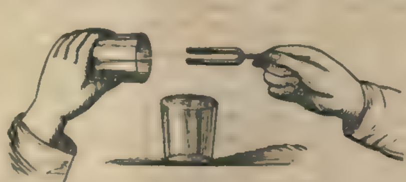
[†] *Ante*, p. 41.

An immense variety of similar effects of colour to those to which we have alluded, is found to occur from a variety of causes. Thus we see the curious play of colours on the surface of melted lead, and heated copper and steel; the beautiful appearance of mother-of-pearl, fringes in thick glass, which, after heating, has been dipped in cold water, &c.: but we must enter more deeply into the philosophy of the question, by inquiring into the laws of what is termed the *interference of light*.

This subject may present some little difficulty at first sight: we will, however, by illustration and analogy, endeavour to make it as plain as we can; and we shall connect the remarks we have often made in reference to the undulation of an ether, as illustrated by sound, and the circles produced in water when a pebble is cast therein. If two sets of waves are produced on the surface of still water, it will be found, that at such places where the waves are of different depths, there they will naturally destroy each other. This is easily seen by casting two pebbles into a pond, at some little distance from each other, and watching the intersection of the waves thus produced. If the two sets of waves are of a similar nature, or in a like phase, their resulting effect will be double that of each taken separately. Now, in the same way as in the cases we have instanced, when an undulation of ether is interfered with by what we may call a half undulation, the result is, that either darkness, that is, absence of light, is produced, or colours varying in their nature, as observed in the spectrum, occur.

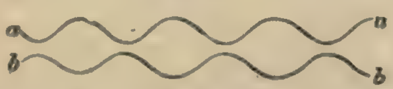
The subject may be still further illustrated by means of a tuning-fork and two glass cylinders. On striking the tuning-fork, and placing it over one of the glasses standing in a vertical position, the air in the glass, and the vessel itself, will also vibrate. If, however, the other glass is placed so that its mouth is at right angles with that of the vertical glass, all sound will immediately cease, owing to the *interference* of the two sets of waves of sound thus coming in opposition to each other. The mode of conducting this experiment is represented in Fig. 28, wherein the glasses are found in that position in which the interference of sound can be effected.

Fig. 28.



Now, substituting ether for the air (so far as light goes) and water in the two instances we have just selected, the student may imagine two sets of waves thus interfering with each other, one of these being represented by the line *a* in Fig. 29, and the other by the line *b*.

Fig. 29.



We here find, instead of the depression and altitude of each of the waves being synchronous, or co-incident with each other, they are actually opposed to each other, and that the difference of the position of each curve of the wave is equal to half an undulation. The result is, that at the end of an undulation, the two waves are in different phases or positions, and *interference* results therefrom.

We might extend our analogical illustration still further if necessary, and compare the different coloured plates produced by the interference of light with the chords which a skilful player on a stringed instrument is enabled to produce by the combination of vibrations of different lengths. We trust, however, that our readers have understood the drift of our remarks, and we shall, therefore, not pursue our explanations to any further extent.

To apply these doctrines, we may add, that the colours of thin plates, &c., are the result of the interference of two sets of *reflected* rays with each other, when such are viewed from the surfaces of the glass plate and lens; and the complementary colours observed by looking *through* the lens and glass, are the effect of the interference of the *transmitted* rays with each other.

We may here explain more fully than we have hitherto done, the meaning of the term "complementary colours." If the eye watch one colour intensely for some time, on removing this from the sight, an image of the object, of an entirely different colour, will be perceived. A simple way of trying this, is by placing a red wafer on a sheet of paper. After looking at this intensely for a few minutes, the eye will perceive a green image of the wafer, if the sight be directed to another place. Sheets of deeply coloured paper answer a similar purpose; and thus, if a person look intently for any length of time on the back of a book or other object of a deep red or yellow colour, a spectral image will be observed, of a green or violet colour respectively.

The colours so observed are complementary to those of the object; or, in other words, are those which, with that of the object, would together produce white light. For the information of the student, we append a table of the different colours of the spectrum, or of any object, and of their corresponding complementaries.

Colour of Object.	Its Complementary.
Violet	Yellow.
Indigo Blue	Orange.
Green	Red.
Yellow	Violet.
Orange	Blue.
Red	Green.

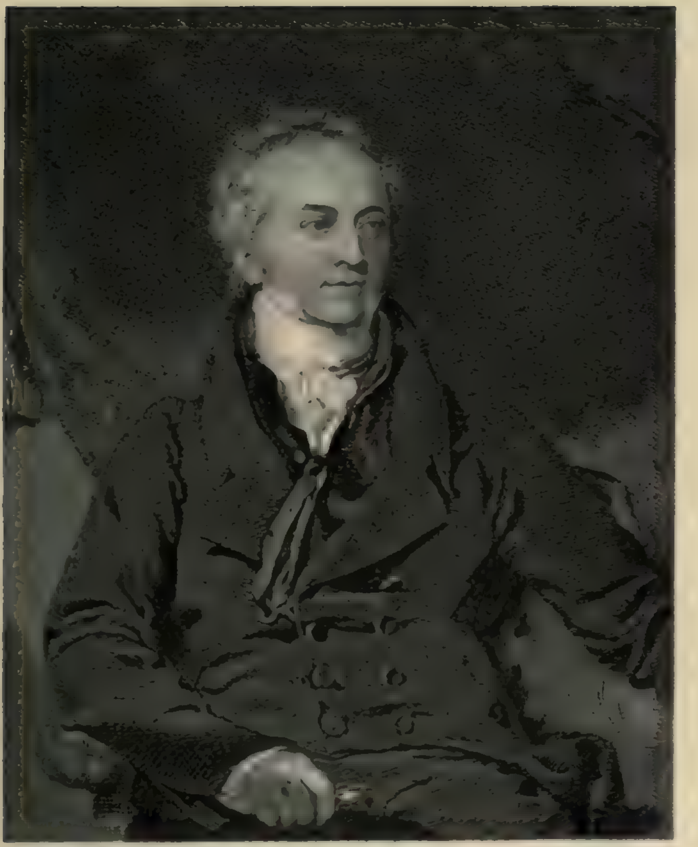
A very interesting application of this property of colours is often made in economic and commercial affairs. Coloured fabrics are generally arranged in covers, or papers of such colours as are complementary to the articles they enclose. Thus a green silk or cotton fabric appears of a far richer colour when wrapped with, or placed on, a sheet of reddish paper, than when placed on a white one. By judiciously choosing such arrangements the saleable nature of the article is often enhanced. This is another instance of scientific laws being often applied by persons ignorant of their existence, who, however, by long practice have blindly arrived at truth. Great taste is often exhibited by ladies in the arrangement of the colours of the different parts of their dress, in their unwittingly following the principles we have laid down. We may here, perhaps, be permitted to become the apologists for some of the fair sex, who do not seem to be characterised with correct taste in this respect. We do so by stating, that it frequently occurs that such have not the optical power of judging of such matters, and therefore are not to be blamed for what, at first sight, would appear to indicate an absence of refinement or judgment. We shall enter more fully into this question hereafter, when we consider certain physical defects in the construction of the eye, which incapacitate many persons, more or less, in discriminating coloured objects.

The law of contrasts of colours, as applied to dress and to commercial purposes, although of great interest, falls scarcely within the scope of our plan. We have, however, much pleasure in recommending the perusal of a work entitled *Colours and their Contrasts*, by M. Chévreul, a French chemist; in which the subject is treated in a complete and masterly manner, and in which all the laws of complementary colours are fully entered into, and their applications judiciously pointed out.

DIFFRACTION.

IN connection with the interference of the undulations of light, we must now refer to the phenomena of *diffraction*, or the production of coloured fringes by means of special arrangements acting on a diverging ray of light.

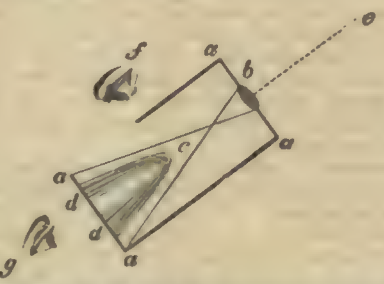
A very easy mode of observing the effects of the diffraction of light, is by admitting into a dark room a ray of light through a short-focus lens, and placing a knitting-



Thomas Young MD
Sec. R.S.

needle at any place beyond the focus whence the rays diverge. If the shadow of the needle be received on a sheet of paper, fringes of coloured light will be observed thereon. A convenient instrument for the purpose may easily be constructed out of a common camera, by removing the ground-glass plate and the mirror, and by replacing the convex lens in front by one of a very short focus—say not exceeding an inch. The opposite end is covered with a sheet of white paper; and the object whose shadow is to be obtained, must be placed between the paper and the focal point of the rays passing from the sun and through the lens. The observer can thus perceive the coloured fringes on the paper by looking through the open door generally found in the old form of the camera. Our annexed illustration will give an idea of the construction of this apparatus.

Fig. 30.



a a a a, represent the usual form of the camera-box; *b*, a lens of short focus; *c*, a needle producing the shadow; *d d*, the coloured fringes received on a paper screen, resting on the end of the box; *e*, a ray of light entering the lens *b*; *f*, position of the eye required to observe the rings by reflection.

The above arrangement, whilst extremely simple, has the advantage of being easily held in such a position as to be at any time in the direct rays of the sun, or of an artificial light. The end of the box, *a d d a*, may be taken out and replaced by a sheet of ground glass, when the fringes may be observed through it, as at *g*, instead of on the surface of the paper screen. The observer will perceive that the white light has been completely decomposed, and the fringes present the same colours as if produced by the glass prism. The first set of fringes exhibits the colours violet, blue, green, yellow, and red; the next, blue, yellow, and red; and the third, the same colours as the second, but fainter in their tint. If the object by which the diverging rays pass be moved to and fro between the light and the screen receiving the fringes, the latter increase in width.

The effects thus observed are to be explained on identical principles with those which we have already referred to when describing the phenomena of the interference of two sets of undulations. And the fringes of colour, or the dark shadows, are simply due to undulations of different lengths interfering with each other. Having already entered fully into the philosophy of the question,* we pass on to consider some modification of these experiments.

Experiment 3.—In the diverging beam place a piece of metal through which a very fine hole has been made by means of a pin's point, and between this and the eye place a convex lens. A circle of beautifully coloured rings will be at once observed, which will expand or contract as the lens is shifted to and fro between the eye and the hole in the metal plate. A piece of thick tinfoil answers as well for this experiment as the metal plate, if a hole be pierced through it, as already described.

A great variety of arrangements, wherein two surfaces placed close together and introduced into the diverging beam, may be employed. Amongst these may be two knives, whose edges are together at one end, and slightly separated at the other; gauze-work, either of vegetable fibre or of metal wires; perforations in any opaque object; and, indeed, any object which by interfering with the continuity of the rays of the diverging beam, will tend to produce the phenomena we have mentioned.

In certain instances, the centre of the shadow will present a black line, or point, where the undulations have destroyed each other by their mutual interference. In other cases a line of white light is produced. The student will here perceive a practical illustration of our previous remarks on the production of light, or its absence, by the motion of the waves of ether being destroyed in certain cases, and intensified in others, just as these undulations do or do not interfere with each other.

It will be noticed that the rays passing from an interfering object are not in straight lines. They follow the curve of a hyperbola, and so reach the screen, as mentioned in our description of the simple apparatus whose use we suggested when introducing this subject.

DISPERSION AND ACHROMATISM.

We have already mentioned, that different transparent media have varied powers in dispersing or spreading the rays of light transmitted through them. We now propose to investigate the subject more fully, and also to refer to a very valuable application of the laws we shall meet with; namely, the construction of achromatic lenses.

If solar light be transmitted through two lenses, one of crown and the other of flint glass, being similar in every respect excepting in the material of which they are made, it will be found that the spectra they produce differ very materially. They affect the length and position of the spectrum produced—that of flint glass acting to the greatest extent in these respects. This is owing to the fact, that flint glass has a greater dispersive power on the rays of light than crown glass. Moreover, it is found, that certain substances extend one end of the spectrum more than others, some having a special influence on the blue, and others on the red rays; and thus either of these predominate over the other, according to the material of which the prism is composed; hence arises that which has been called the irrationality of the spectrum.

As we have already remarked, two prisms of different material may be so arranged, that the light passing through them shall not be separated into a spectrum, and but comparatively little coloured light will thereby be produced. By an analogical process, achromatic lenses are constructed; that is, lenses which do not give coloured images such as those which one material always affords.

To understand what is called "chromatic aberration," or the cause of these coloured images when ordinary lenses are employed, the student may receive the rays of the sun through a lens on a sheet of white paper. If the light reach the paper at a less distance than that at which the general focal point exists from the lens, then he will perceive a ring of a blue colour. If the paper be placed further from the lens than the focal point, then a red ring will be observed. This effect may often be noticed when the lenses of a common magic lantern are being focussed, the light proceeding therefrom being received on a white screen. A red, or blue hazy colour is thus produced, and is an instance illustrating the fact, that the red and blue rays focus at different points after proceeding from the lens, owing to unequal refrangibility. This effect is what is called *chromatic aberration*.

The student will observe the general effect of chromatic aberration by looking at an object through a common lens, when he will perceive the external parts of the image to be coated with coloured fringes.

This gives rise to great inconvenience when such lenses are employed in telescopes, microscopes, photographic cameras, and other optical instruments. However, a knowledge of the cause of any defect very often suggests its remedy; and this occurs in reference to the subject with which we are now dealing.

It has been found that, by combining lenses composed of materials having different dispersive powers, a single lens almost achromatic—that is, giving no coloured images—may be produced which affords a focus where all the rays meet simultaneously. In practice, this is done by combining a flint with a crown or plate glass lens. In some instances more than two lenses are employed;

---

* See *ante*, p. 52.

and the result is, that the coloured fringes are almost entirely neutralised, the lens becoming perfect for all the purposes of the optician.

Fig. 31.

We shall defer entering into the great value and essential nature of these improvements in the construction of lenses, until we deal with optical instruments. It will be desirable, however, that the student should fully master the principles which we have here explained, so as to avoid the necessity of circumlocution, on our part, when we have to refer to their applications.

Fig. 31 represents a section of an achromatic lens; wherein a double concave lens of flint glass, *a*, and a double convex one of crown glass, *b*, are united together.

EPIPOLIC DISPERSION.

A PECULIAR kind of dispersion of light is effected by some substances both in a solid and liquid state; which, from its connexion with the chemical rays of the spectrum, has become a subject of considerable interest in the science of Optics.

If a solution of sulphate of quinine in dilute sulphuric acid be poured into a glass of water, it will be observed that a peculiar blue tint pervades the liquid, whether it is viewed by reflected or transmitted light. The attention of scientific men was first called to this effect by Sir J. F. W. Herschel; and it has been since fully investigated by several physicists.

Similar effects to those produced by the solution of quinine may be observed in an infusion of the bark of the horse chesnut; the green colouring matter of leaves, obtained by leaving them some considerable time in spirits of wine; a solution of the colouring matter of some kinds of sea-weed; glass coloured by the oxide of uranium, &c. We have lately noticed the epipolic appearance whilst pouring semi-congealed oil from a glass bottle, and also when the juices of some kinds of lemon are squeezed into a glass of cold water. The cause of this phenomenon is a peculiar and internal dispersion of the refrangible rays of light. Indeed, Professor Stokes shows that the refrangibility of some rays is changed. It is found, that light which has thus been affected, has not the power of transmission through a solution similar to that which has been employed to produce it. Thus, a solution of quinine placed in a glass vessel, and viewed through another vessel containing a similar solution, does not present the blue appearance which may be seen when it is viewed alone. In other words, the passage of the epipolised rays is completely stopped by the second solution. The investigations which have been made on this subject have much assisted in illustrating the nature of the rays of light existing *beyond* the visible portion of the spectrum, where the chemical power of light is found to be most active. To this we shall further allude under the head of Photography, when we enter into the philosophy of the various processes involved in that interesting application of the effects of light.

Having thus pointed out some of the chromatic effects resulting from the interference of rays of light and the undulations of ether, as producing these effects, we now proceed to investigate a series of singular and interesting phenomena connected with mono-chromatism, and the production of Fraünhofer's lines or spectral bands. We shall also introduce an account of a very interesting discovery made by continental chemists; from which we shall not fail to observe how close is the connexion between the matter with which we are surrounded, and those forces which are at once latent in it.

MONO-CHROMATIC LIGHT.

IN previous pages we have supposed that ordinary white light has been employed for our experiments and investigations. Under certain circumstances, however, a variety of interesting phenomena is presented when light of a single colour is used. Mono-chromatic light, as its name indicates, simply presents one colour to any object on which it falls; and such objects, therefore, only reflect that colour in its simple or partially modified state, to the eye viewing them.

As all the objects generally perceived by the eye are seen by the aid of white light, which (with comparatively trifling exceptions) is composed of the colours presented by the spectrum; it may be well that we should afford some instances which will illustrate the peculiar phenomena arising when single-coloured light is similarly employed. For this purpose the following experiments may be tried.

Experiment 4.—Put a table-spoonful of common salt into a glass bottle containing two ounces of strong spirits of wine, and agitate them together until as much as possible of the salt is dissolved. Pour some of the clear solution on a piece of tow or on a sponge, and inflame it in a room where no other light is present. All objects of a light colour will present a pale yellow tinge; whilst those of a dark tint, such as deep blue, &c., will appear of a gray or black colour. The human face presents a most ghastly appearance when viewed by this light, simply because it reflects no colour except that afforded by the burning spirit.

Experiment 5.—Hang a few light-coloured ribbons on a stick, and view them by means of the light produced in the last experiment. If light prints, yellow, and orange are used, each ribbon will present the same colour, owing to the mono-chromatic nature of the light employed.

Experiment 6.—After observing for a short time the effect of this colour on the ribbons, introduce the light of a candle. This source of light being nearly equal to white light, will represent the original and natural colours of the ribbons.

As some of our readers may be desirous of repeating this experiment in public, or as a class illustration, we may mention, that the best mode of so doing is, by burning a large quantity of the spirit on a piece of tow; and instead of employing ribbons, a very effective mode is that of clothing the upper part of the experimenter with folds of glazed calico of different colours. The effect on the face and the clothing is thus perceived simultaneously. If the oxy-hydrogen light be then suddenly thrown on the operator, or the light of a powerful gas flame, the original colours will be at once restored. They are, of course, immediately lost on the extinction of the white light, and subsequent employment of the mono-chromatic. This, if well managed, forms an excellent experiment for the lecture-table; and is a good illustration of the effects produced by either the presence or absence of those rays which are essential for viewing bodies in their ordinary state.

Other solutions of salts in alcohol produce flames which have characteristic colours. Thus a solution of nitrate of baryta or boracic acid in spirits, produces a flame of a green colour; and nitrate of strontia gives one of a rich red colour. In the same manner these salts afford rich green or red flames when burned with charcoal; and, under the names of green and red fire, are largely employed in theatrical representations for numerous scenic effects. By the use of these mixtures the transformation scenes of the pantomimes are always illuminated. We have already referred to the effects produced on the natural colour of bodies by the spectrum at a previous page;* and that, with the experiment we have just mentioned, afford illustrations of the effect of single-coloured light.

We have supposed that ordinary artificial light is identical in its physical character with that of the sun; but such is not actually the case. The nearest approach which we have to solar light is that produced by means of charcoal points, forming the terminals of the voltaic battery. This light (commonly called the electric light) is one of great intensity; and every coloured body appears, as near as possible, of the same tint as when viewed by means of sunlight. The lime light comes next in order, with respect to the purity of its rays; but is much inferior to the electric light. A very beautiful white light is produced by burning phosphorus in a jar of oxygen gas; which has a similarly optical effect to that produced from the two previously named sources.

---

* *Ante*, p. 49, *et seq.*

When certain colours, especially blue and green, are viewed by means of a gas or candle flame, it is found that, in many instances, the actual tint is quite lost; for some blues when thus seen appear of a green hue. This is owing to the predominance of the *yellow* rays in the source of light; which, by mixing with the colour reflected from the object, produce a green hue. We have already explained the reason of this when speaking of the prismatic spectrum, as a result of the overlapping of two colours. In commerce, it is therefore impossible to judge of natural colours by ordinary artificial light; and this is well appreciated by ladies in purchasing articles of any intermediate spectral tint. This fact is another, though partial, illustration of the laws of mono-chromatic light.

In connection with this subject, and also with a discovery made by Fraünhofer, we shall introduce some remarkable facts lately published by MM. Bunsen and Kirchkoff. These gentlemen, by means of the prism, have been enabled to identify the peculiar colour of the vapour of each metal whilst the solid is undergoing combustion. Most of our readers will be familiar with the colours produced by some metals when undergoing combustion—as seen in the blue flame of zinc, the red of strontium, and the green of barium. Instances of the two latter we mentioned in the previous page. Now these are easily distinguished from each other when separately in combustion; but the eye might fail to detect their presence when they are burned in contact with other substances. As, however, each coloured or mono-chromatic light has a peculiar effect of its own in producing a special spectrum when refracted by a prism, MM. Bunsen and Kirchkoff have availed themselves of the fact, and have thus made the prism an instrument which may be employed as an agent in chemical analysis. As the discovery has only been made public but recently, we cannot, at present, afford more information than that which we append, and which is a condensation of their published experiments, extracted from the *London Review*, of January and March, 1861.

"MM. Bunsen and Kirchkoff have, by a complicated arrangement of prisms and telescopes, arrived at such certainty and delicacy in their results, as to be able to see, by a glance at the most complicated mixture (of burning metals), through the eye-piece of their instrument, its constituents ranged side by side, each individual metal glowing with its own peculiar colour. By thus removing the interfering action which coloured fires would naturally have if all were united and burnt together, they were at once placed in possession of a very delicate method of chemical analysis. Not only could they have visible proof of the existence, in any mixture, of a body capable of giving a colour to flame; but this effect was produced by such an inconceivably minute quantity of the element as the mind almost fails to comprehend—the one hundred millionth part of a grain being thus capable of detection. During their examination of these phenomena, every mineral substance which came to hand was optically interrogated in this searching manner, and in all cases with remarkable results—bodies which had hitherto been looked upon as so rare as to be merely chemical curiosities, being seen to form constituent parts of most rocks, soils, and waters. Some mineral waters, however, gave results which could not be accounted for by any of the previously observed facts; a new colour starting up before their eyes, and occupying a hitherto blank space in the glowing row of metals. Evidently this was a new element, which has thus revealed itself to an optical inspection.

"The next point was to collect some of the unknown body. * * * * After boiling down twenty tons of mineral water, and submitting the residue to various chemical agents, the latest accounts report that they have at their disposal upwards of one hundred grains of cæsium; this being the name under which the new metal enters the domain of science, given to it to recall the colour which it communicates to flame."

In another number of the same periodical (March 30), a further account has been published respecting these interesting facts; from which we make the following extracts:—

"Mr. Crookes, the editor of the *Chemical News*, has just discovered that the sulphur group of elements contains another member. The appearance shown by the spectrum of this new body, when a little of it is burned in a gas flame, is very remarkable; and, as the discoverer has repeated before us many of his experiments in his laboratory, we are enabled to give a full account of the grounds upon which he bases his claim for the elementary character of this newly discovered body.

"Nearly every elementary substance in nature (and recent developments of this branch of science would almost warrant us in saying *every* element) possesses the property of imparting certain colours to a flame, provided that the latter is hot enough to volatilise the body; and this holds good not only with the elements in the free state, but to all their compounds. When these colours are examined by a prism, in an appropriate spectrum apparatus, they are, in most cases, resolved into a series of brilliantly luminous lines of every conceivable tint and colour—some sharp and defined as if ruled by hand, others shaded off at the edges, and having a nebulous appearance; but each system of coloured bands being invariably associated with the same element, and thus being as accurate a test of its presence as the most rigid chemical analysis could devise: in fact, far better; for chemists, being human, may err; whilst the laws of light and refraction can never fail." * * * * * *

"The new body which we have mentioned above as having been just discovered, came to light in this way. A new mineral from the Hartz mountains having given some very discordant results in ordinary chemical analysis, a portion was subjected to spectrum examination, when the disturbing cause was at once seen in the shape of a beautiful green line, glowing on a pale background of the same colour. Our experimentalist having an intimate knowledge of the appearances which the bodies present ought to give, at once pronounced this line to be an interloper, and set to work to isolate its cause. After numerous trials and failures, constantly appealing to the spectrum for information as to how the stranger behaved under the various and unusual methods of treatment to which it was being subjected, success at last crowned his effort, and Mr. Crookes is now the happy possessor of a whole grain of the new element. The appearance of its spectrum is very striking. The discoverer stationing himself at the gas-burner, placed us in front of a powerful telescope, with which the instrument is fitted. At first, only the green and blue bands due to the gases in the burner were visible; but suddenly a bright flash of green light illuminated the field of view, and the new element was glowing before us as a sharply-cut brilliant green line, on a jet-black ground. The only elements which at all give a similarly striking spectrum, are sodium and lithium; and the equally beautiful lines of these, which were afterwards exhibited simultaneously with the green line, are in entirely different portions of the spectrum, besides being of different colours—one being crimson, and the other yellow."

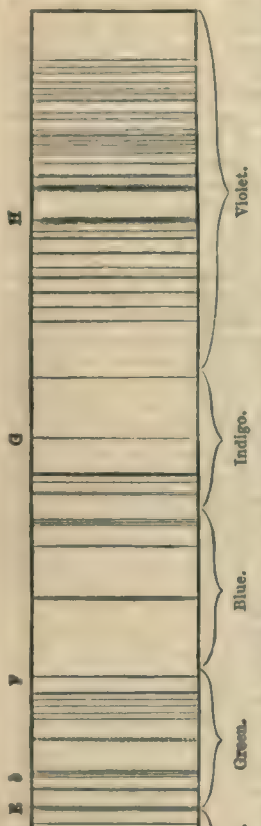
These results are obtained by viewing the spectrum produced from the flame by means of an achromatic telescope, which is employed in a similar way to that we shall presently describe as adopted for viewing Fraünhofer's lines. We need scarcely add, that this discovery, although still in a crude state, is of the highest importance in experimental science, and promises to add largely to our stock of knowledge of the chemical characters of elementary bodies, and also to add to their number.

FRAUNHOFER'S LINES.

It was discovered by Dr. Wollaston, and independently by M. Fraünhofer, that there exists, throughout the length of the spectrum obtained from any source of light by means of a flint-glass prism, a number of black bands or lines, which cross the spectrum perpendicularly to it. One of the most surprising facts connected with these lines is, that their number and position vary for every kind of light. Thus, there is a set of lines for solar, lunar, and planetary light; which being obtained from the same independent source, the sun, are productive of identical bands; whilst the light of the fixed stars, of coloured flames, &c., each presents these bands in different numbers or positions when compared with each other, or with solar light.

Bearing in mind the remarks which have been made in reference to the discoveries we mentioned in the previous section, the reader will not fail to perceive, that this phenomenon of spectral lines is of great importance both in physical and chemical researches: we shall, therefore, endeavour to explain their characteristics, and to afford an opportunity for the student to observe them, by describing an apparatus which will answer that purpose.

Fig. 32.



In the annexed engraving we have an illustration of the appearance of these dark lines, as obtained from solar light. We have, however, represented but a small number of them, because the limited size of our page would not admit of a greater extension.

We are indebted for the annexed cut to Sir J. F. W. Herschel's article on light, in the *Encyclopædia Metropolitana;* and it affords the reader a representation of the mutual position and comparative frequency of these bands in a spectrum of solar light; and showing, at the same time, their connexion with the different coloured rays. The Roman capitals at the upper part of the diagram show the position of the larger and more defined lines; the italics represent narrower lines placed close to each other. Between the capital letters numerous fine lines are exhibited; and their position in reference to the coloured rays is indicated by the names of those rays at the foot of the engraving. In all, about 1,000 lines have been counted as existing between each end of the spectrum.

Our remarks on interference* will prepare the student to understand the cause of these lines. We there stated, that when undulations of different phases, either of sound or light, met each other, or rather, perhaps, united together, the result would be their mutual destruction. Now there is no doubt that these black lines arise from a somewhat similar cause; and as they show the absence of light at any particular point where they exist, we can but conclude, that certain undulations which would, if unimpeded, have produced light in such places, must have been destroyed, lost, or absorbed from the rays incident on the refracting prism during their passage from their source.

We have already remarked that every light presents a different series of these lines. In some they are comparatively absent, or are differently placed. On reflection, we cannot but perceive a most astonishing instance of design in that in which we could least have expected to have discerned such. Every ray of light can be identified from its fellow; and there is not a greater distinction between human faces in different nations than exists here. The generic likeness is complete, but the individual characteristic and difference are not less so.

We have, at a previous page,† entered fully into the laws of single refraction; and also explained how the index of refraction may be found for various bodies. Fraünhofer applied, however, the position of the black spectral lines to ascertain still more accurately the refractive indices of different media. The principle of this system will be easily understood, if the student bear in mind that, if the rays of the *same kind of light* are refracted through *different transparent media*, then the black lines thus produced by each medium differ in their distance from each other according to a fixed law. Now, by comparing these mutual distances in terms of each colour of the spectrum, the refractive and dispersive power of any body can be ascertained, and measured with mathematical accuracy.

It would, of course, be impossible for us to illustrate, by means of engravings, this most interesting fact. Such is entirely a work for exact experimenting, and can only be conducted by those who, through long experience, are prepared to enter into such delicate researches. Having, however, given an exposition of the principles on which these investigations are conducted, we proceed to describe the arrangement which may be employed for the purpose of viewing these lines, and in measuring the distances between them.

Sir John F. W. Herschel recommends that the lines should be viewed by means of a good achromatic telescope. For this purpose, by means of which a magnified view of the spectrum is gained, the colours obtained by the use of the prism‡ are allowed to fall on to the object-glass of the telescope. The lines, which are too close together to be seen by the naked eye, being magnified, may thus be easily perceived, and those in each colour of the spectrum may be separately examined. In using the telescope, the object-glass takes the place of the screen usually employed to receive the spectrum rays.

Mr. Ladd, of Beak-street, London, has lately manufactured an apparatus, constructed on the same principles as that which was employed by MM. Bunsen and Kirchkoff, which can be used also to discover the presence of M. Fraünhofer's lines in various spectra. It is a modification of that which we have just described, and will, doubtless, prove of great value as an instrument of research in the new branch of what we may call Optical Chemistry.

THE EFFECTS OF LIGHT ON ORGANISED BODIES.

In a former page§ we have noticed, generally, the effect which light has on the colour of vegetable and animal bodies. We here propose to enlarge on that interesting subject, and to suggest some experiments which may easily be repeated by the student.

The most cursory observation of the appearance of plants in a growing state, is sufficient to show that light has a great influence on them. This may be well observed in a garden whose walls run east and west. Plants growing on that side which is shaded from the solar rays will be found generally in a sickly state, and their flowers, fruits, &c., are few, and imperfect in their development; whilst those growing beneath the north wall, with a southern aspect, and thus continually exposed to the full rays of the sun, reach their proper maturity and size.

We may also notice that plants, trees, &c., invariably shoot out more branches on the side on which they are exposed to the sun. This may be well illustrated by placing a geranium or other quick-growing plant in a window with a southern aspect, and retaining it in one position for two or three weeks. It will be found that numerous shoots spring out towards the window; whilst that portion of the plant which is not exposed to the external light, scarcely evinces any sign of growth. If, however, the shaded portion be turned round, it will, owing to the action of light, soon show active signs of life, and will rapidly bud forth. The common hollyhock, which has a long stem, may be thus twisted into a screw-like shape by exposing its sides alternately to light. Its tall stem gradually bends towards the sun during its growth, and it may thus be cited as another and excellent illustration of the effects of light on the growth of plants.

---

* See *ante*, p. 52.

† See *ante*, pp. 45, 46.

‡ *Ante*, p. 49.

§ *Ante*, p. 50.

Even by means of artificial light, plants may be grown which will present nearly the same colours as they would if freely exposed to the rays of the sun. A geranium plant may thus be brought up by confining it in a place excluding the light of day, if a powerful light, such as from a paraffin or gas lamp, be employed. This interesting experiment may easily be repeated by the student if a little care is exercised. To show the effect of even artificial light, two equally healthy plants should be chosen, and whilst one is exposed to the light of the lamp, the other should, for an equal space of time, be entirely secluded from light of any kind. The latter will speedily fade, whilst the former will flourish pretty well.

Now, it is found that certain of the rays of light have more effect on germination and growth than others. Mr. Hunt tried a very ingenious experiment for proving this. He cast the rays of coloured light obtained in the usual way from a prism upon some cress, and found that that portion of the plant growing under the *blue* rays grew vigorously, whilst that under the red rays bent away from them as from the face of an enemy.

One of the simplest modes of trying this experiment, is that of exposing cress seed to coloured light, produced by passing white light through glasses of different colours. Three portions of common cress may be placed behind a piece of red, yellow, and blue glass respectively, and the relative effect may thus be readily observed. Since the discovery of the chemical effect of the blue rays of light, the principles to which we have alluded have been put into practice in the construction of greenhouses. Instead of using white glass, which permits the flow equally of all the rays of light and heat, greenish or blue-coloured glass is now much employed, and great advantage thus arises in respect to the growth of the plant, and the production of its flowers and fruits.

The spectrum, however, as we have already remarked, presents rays having three characteristics—the red being associated with the heating, the yellow with the luminous, and the blue with the chemical effects of light; and each of these emanations has a specific office in connexion with vegetable life. It has been stated, as the result of experiments by Dr. Draper, of New York, that the yellow rays assist the nutrition of plants, whilst the blue rays are essential to their movements or expansion in size or direction.

Without entering, at present, into the department of organic chemistry, we may state, that all plants thrive through the chemical changes which their organisms effect on the carbonic acid contained in the atmosphere surrounding them. It may appear paradoxical to those unacquainted with the many astonishing facts presented to the philosopher, when we state, that the greater part of plants, from the creeping moss on our garden walls, to the stately oak tree of our forests, is obtained not from the earth by their roots, but is actually received from the air, by the decomposition of the carbonic acid, and the assimilation of its carbon or charcoal to the body of the vegetable. During the day-time, the rays of light assist and give vital energy to the plant. Its leaves absorb the carbon from the carbonic acid, and set free the oxygen which is combined with it. They thus literally live on air. In the daylight, all plants give off oxygen; whilst at night, their vital force being diminished in intensity, they are found to undergo a partial decomposition, and to *give off* carbonic acid gas.

To popularise still further these interesting principles, we may state, that by excluding light entirely from a growing vegetable, we as effectually destroy its chance of vitality and growth, as we should do in the case of a human being by sinking him in a pond of water. Indeed, the analogy is quite complete, because the cause of death is identical; namely, the asphyxiating effect of an undecomposable gas on the "lungs" of either object.

We cannot omit here to mention a beautiful illustration which is found in this instance, of the universality of design in nature. All animals expire from their lungs carbonic acid gas, which is to them a deadly poison. The lungs—that is, the leaves of trees—actually breathe this poison, and, assisted by the rays of light, they decompose it, returning to the air the oxygen, which is to us its vital portion, and retaining the solid part, or carbon, for their own subsistence. Thus, what we poison, the plant purifies, and a grand compensating action is continually kept up between the products and requirements of the animal and vegetable kingdoms.

The cause of those peculiar effects produced on vegetable and other objects by the blue rays of light, and to which the chemical changes observed in the photographic process are due, has been termed *actinism;* and when we refer to the *actinic rays* of light in our future pages, the reader will understand that we speak of those which have the powers to which we have here alluded, in contradistinction to those of the luminous and calorific rays of the spectrum, which do not possess them.

To render our remarks better understood, we here introduce a diagram, which will give a clear idea of the relative position and space occupied by those three classes of rays in the spectral image, as received on a screen; as also of those rays which extend beyond the visible spectrum, both at the red and blue apparent terminals. (See Fig. 33).

D

In this figure we observe, on the right-hand side, at the top, the place of the epipolic rays, to which we have already alluded.[*] Below these we have the lavender, violet, indigo, and blue, which are the chief seat of the actinic, or chemical rays of the spectrum. This is indicated at E, on the left of our engraving. The green rays, which seem to form the middle of the spectrum both in a physical and in actual position, are succeeded by the yellow and orange, which are those most luminous in their character, as shown at C. Following these are the red rays; in which, as at D, the heating effects of the prism are most manifest. The student will thus, by studying the above engraving, be enabled to experimentalise directly with any of these three classes of rays independently; and of thus repeating some of the interesting effects of coloured light on plants, &c., which we have already named. With respect to the extension of the rays beyond the spectrum at B, it is found, that the actinic or chemical effect is active, as are the calorific effects beyond A. These represent the position of rays which cannot be observed by the eye, but which are respectively discovered by placing paper coated with chloride of silver beyond B, and a thermometer beyond A, when these peculiar properties will become evident. Progressing below the spectrum at A, and still further from the red rays, we shall gradually arrive at another spectrum, wherein the red of the first will merge into the extreme blue of the second; and hence, after passing the last heating in red rays, these are necessarily succeeded by others of an actinic nature, or capable of producing chemical changes.

---

[*] See *ante*, p. 54.

In our section on Photography we shall have to avail ourselves of these principles to a large extent. We must, however, to save space, presume that our readers will at this point fully master the details of our analysis of the spectrum, and thus render continual repetition on our part unnecessary.

Before leaving this interesting subject, we recommend the student to try the following experiments, which will tend to impress the truths we have stated on his mind.

Experiment 7.—Prepare a strong solution of sulphate of copper in cold water, and add liquid ammonia to it until all the precipitate is dissolved, and a rich blue colour produced. Pour this into a flat glass vessel, and allow the rays of sunlight to pass through the liquid, and to impinge on a piece of paper coated with chloride of silver. This is made by dipping one surface of a sheet of white paper into a solution of common salt, and, after drying it, the salted side is placed in a solution of nitrate of silver, and subsequently dried. The actinic rays of light pass freely through the solution, and will speedily turn the paper black.

Experiment 8.—Repeat this experiment, but employ a weak solution of bichromate of potass in cold water. The prepared paper will scarcely change at all; because, in this instance, the liquid permits the luminous and calorific rays to pass, but entirely stops those of actinism.

Experiment 9.—Prepare three solutions—one as in Experiment 7; another as in the last experiment, so as to be of a rich yellow colour; and another with the same salt, so as to give a deep orange or red tint on looking through it. Expose at the back of each of these solutions a small thermometer, so that its bulb may receive the transmitted rays. That behind the blue solution will exhibit no increase of temperature; and that behind the yellow one will not indicate any extraordinary change; while that which receives the rays from the red solution will speedily evidence that heat easily passes, and that to a very much greater extent than through the two other liquids.

It will thus be perceived, that the three effects of light may be separated from each other; or, in other words, that which we conventionally call "light" may be divided into three phases, so far as its effects are concerned; namely, those of actinism, luminosity, and caloric.

We here append a few instances in which the action of the rays of light effect either physical or chemical changes on some substances; indicating, at the same time, the nature of the change which is produced. We, however, need scarcely remark, that our list is only illustrative, and, of course, far from exhausting the almost infinite number of such changes which are constantly occurring in nature, although they are rarely observed by us, because they take place so gradually. We shall omit those which more particularly pertain to photography, because such will come under our consideration when we treat on that subject.

The Human Skin.—Every one is familiar with the fact that the natives of the tropical regions are generally of a colour approaching to black. There are many causes which tend to produce this appearance besides that of light; and as such pertain rather to physiology, we cannot, of course, enter into their consideration in this place. We shall, however, deal with them in our section under that head, and also under Ethnology. We need scarcely remind our readers, that a lengthened exposure to strong sunlight, of inhabitants of temperate regions, has the effect of darkening the colour of the skin. This takes place most readily with persons whose complexion is fair. Light, however, has not only a colouring effect, but also must be regarded as having a decided sanitary influence on all constitutions. We hence find the ruddy and healthy appearance of out-door labourers, of sailors, and locomotive engineers. Instances are on record of persons who, having acquired deformity and disease through close confinement from daylight, have been speedily restored to health by subsequent removal to places where free exposure to the sun was obtained. Our experience of the beneficial effects of a temporary residence at the sea-side, is another illustration of this result; and such arises not simply from a change of air, but also from the fact, that the rays of the sun shine purer, and more free from loss and absorption of their actinism, when passing through an unclouded atmosphere, than through the smoke of our large cities. We have repeatedly tried experiments, during the same day, in different parts of London and Glasgow, with photographic apparatus; and have been surprised to find the variation of time required to obtain a good image on a sensitive plate, at places respectively free from, or beclouded with, the smoke of the city. Any one, especially of a fair complexion, may repeat these trials in a rough but interesting manner, by walking for an equal length of time, on two clear days, during the heat of summer—on one in the streets of a large city, and subsequently in the open country adjacent to it. In the former instance the skin will be scarcely affected; whilst, out of town, an exposure to sunlight will often prove extremely painful, from its action on the skin of the face and hands. That such is the effect of light, and not of heat, is evident, inasmuch as the red heating rays are more prevalent under the smoky sky than in a clear one. The former absorbs, whilst the latter permits the free passage of actinic rays; hence the results to which we refer. We may, perhaps, be permitted to adduce an illustration which we afford, individually, of this effect. Whilst experimenting, some years ago, with the substance found in the Russian "infernal machines," we had the misfortune to receive serious injury from the sudden combustion of several pounds' weight of chlorate of potass and sugar; by which the face and hands were severely burnt. Although not the least external evidence exists of this at the present time, an exposure of a few hours to a summer's sun induces extreme pain, whilst we never find the least inconvenience from the intense heat of a wind or steam-boiler furnace. We have also observed, that the electric light from a large voltaic battery has a similar effect, even although we may not perceive the least sensation of heat. We have named this as an interesting physiological fact, and one which we trust that none of our readers may ever be in a position to verify.

It has been stated by Dr. Edwards, that tadpoles, if entirely deprived of light, are never changed into complete frogs, but remain growing in what we may term the tadpole state. Without affirming the exactness of this statement, we adduce it as one which is frequently quoted in illustration of the effects of light.

We have already referred to the fact, that the changes of colour both of the leaves and flowers of plants, are due solely to the action of the actinic rays. We may here add, that some gum-resins are much acted on by the same agency: amongst them, as a good example, we may name guiacum, which becomes of a green colour when exposed to the light of the sun.

So long as flowers retain their vital state, the brilliancy and richness of their colour is enhanced by light. When, however, their tint is conveyed to fabrics, as in the process of dyeing, such colours speedily fade on exposure to the solar rays. Pink and rose-red colours, produced from safflower, and the blue colours afforded by litmus, are instances of this kind. Tincture of litmus, which is often employed in thermometers, and which although in a vacuum where no ordinary chemical change could take place, often loses its colour. This, however, is speedily restored by exposing the litmus to the action of the oxygen in the atmosphere.

Many chemical compounds change their colour or character from the action of light. Nitric acid, if very strong, will thus be decomposed, and become of a deep yellow tint. Chlorine and hydrogen gases will rapidly unite when exposed to the sun's rays. White paint is often darkened only in those places on which solar light has long impinged; and, similarly, the effects of light are observed on nearly every surface which has been artificially coated with the colours usually employed by house-painters, their hue being either increased or diminished. Some of these effects, however, are due partly to other agencies, which modify, although they do not prevent, that to which we have alluded. White-lead paint thus always becomes of a dark colour, in the presence of sulphuretted hydrogen gas, which, with the lead, forms a sulphide of that metal.

Besides being affected by the purely chemical or actinic rays, many plants seem susceptible of what we may almost call a nervous influence, from the presence or absence of light. Some flowers droop and close during full sunshine, and others close in its absence. Instances of this kind are common in our gardens, and may be observed in the flowers of the evening primrose, the marvel of Peru, the marigold, the convolvulus, and several others. Of all these, however, the sunflower is the most extraordinary for its apparent affection for solar light; and hence its name.

OCULAR DEFECTS IN RESPECT TO COLOUR.

Individuals are occasionally met with who are quite incapable of distinguishing the difference between colours, and who ascribe names different to those applied to any colour by persons unaffected by this peculiarity of vision. One of the most remarkable instances of this kind was that of Dr. Dalton, the eminent chemist; of whom it is amusingly related, that having on one occasion purchased, as he thought, a pair of gaiters of a *drab* colour (he being a member of the "Society of Friends"), was remonstrated with by a "friend," who found him walking through Manchester with those of a *flaming red*.

Some interesting experiments are detailed in Sir J. F. Herschel's *Treatise on Light*, which were tried on a person thus affected. So as to secure the true complementary colour to each presented to the eye in succession, polarised light, transmitted through various thicknesses of plates of mica, was employed. By these means, it was found that the blue and yellow colours were those which were best distinguished; whilst all others, including pure red and compounded colours, were either confounded with each other, or named differently to their usual titles. Sir J. F. Herschel sums up the results of this in the following manner:—"It appears that the eyes of the individual in question are only capable of fully appreciating blue and yellow tints, and that these names uniformly correspond, in his nomenclature, to the more or less refrangible rays generally; all which belong to the former indifferently exciting a sense of 'blueness,' and to the latter of 'yellowness.'" In some cases red is confounded with green, green with brown and red, and violet with blue.

It is difficult to give a reason for this strange affection; but, perhaps, it can be accounted for on the supposition, that the defect lies not in the mechanical construction or chemical composition of the humours of the eye, but rather in some affection of the brain, so far as its optical sense exists. Instances have occurred in which disease has produced the effect. We met with a case, some years ago, of a friend who lost the power of distinguishing colours, and the sense of smelling, owing to a fall which injured the back of the head. The injury, however, produced no other permanent result than those we have named. We regret that, owing to the death of this gentleman, we cannot furnish more accurate and extended statements of the facts of his case. Considerable benefit would accrue if individuals thus affected would forward statements of their peculiarities of vision to scientific men. Such would not only add to our own stock of facts, but, by the variety of cases, it might happen that some remedy would eventually be discovered. This might be done without the publication of the names of individuals; their statements being guaranteed by a respectable medical practitioner, as a precaution against incorrect detail or wilful misrepresentation.

OPTICAL INSTRUMENTS.

We now proceed to apply the laws which we have been previously explaining; and if our readers have succeeded in mastering the statements and doctrines we have been investigating, they will have little difficulty in understanding the use of the philosophical instruments we are now about to describe. Although in these we shall find alike the toy of the child and the splendid instrument of discovery of the astronomer, still each and all depend, both in their use and construction, on the laws of the reflection and refraction of light.

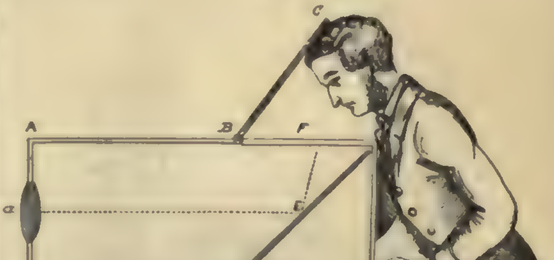
Still pursuing our plan of passing from known to unknown matters, we commence with the Camera Obscura, as one of the simplest of optical instruments. We shall then pass on to the Magic Lantern, Phantasmagoria, Dissolving Views, &c.; thence to Microscopes, simple and compound—the oxy-hydrogen and solar; Telescopes, refracting and reflecting; and shall then describe minor arrangements, such as the Kaleidoscope, Debusscope, Kalotrope, the use of concave and convex mirrors, with others which we need not mention here.

Besides detailing the construction of the instruments, we shall give extended directions for their general management, repair, &c.; affording our readers the results of some experience in the practical use of each, under the belief that many persons who may peruse our pages will be desirous of availing themselves of as much information as we can offer on the subject.

THE CAMERA.

One of the most simple and easily constructed of all optical instruments, is the camera obscura; and of this there are several kinds. The higher class of instrument is chiefly employed for photographic purposes; and as great attention must be paid to the character and make of the lenses and their adjustment; and as its value also is only to be properly appreciated when employed for the purposes we have named, we reserve its consideration for that branch of our remarks included under the head of Photography.

Fig. 34.



A camera obscura, for ordinary purposes, may be thus made:—Into one end of an oblong box, A, say a foot long, eight inches wide, and six inches deep, fix a double convex lens as at *a*, in Fig. 34, which gives a sectional view of the instrument. A piece of British plate looking-glass must be fixed at an angle of 45°, as at E, so as to receive the rays of light passing from the lens *a*, and at a distance dependent on the focal length of the lens. The top of the box must have a flap fitted into it, and fixed on a hinge as at B C; and between B and the edge of the box a piece of ground glass or thin paper must rest, so as to receive the rays passing from the reflecting mirror E, and which are thus spread over the glass at F. The inside of the box should be blackened, so as to prevent the reflection of its sides from marring the picture. If an arrangement of this kind be placed with the lens *a* turned towards any object, the image of the latter will at once appear on the ground-glass plate at F; and if a piece of paper be placed thereon, an excellent outline or drawing of the image may easily be taken, by simply tracing the lines and shading by means of a blacklead pencil.

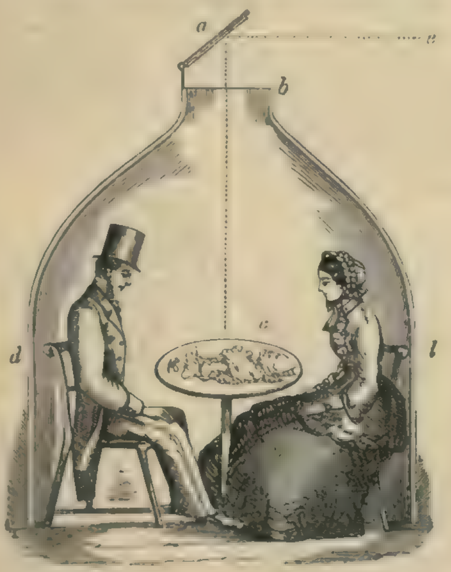
No difficulty need be experienced by any one in constructing a camera of this kind, because the position of each part of the apparatus can easily be arrived at by trial. We may, however, point out two chief matters which should be attended to; namely, let the distance of the lens *a* from the mirror be a little beyond that which would permit its focal point to touch the glass;* and secondly, care must be taken that the glass mirror is properly adjusted, both for receiving the image from the lens, and of transmitting it to the ground-glass plate placed over it.

The above instrument is an exceedingly valuable one for teaching the art of landscape sketching to young persons. The idea of distance and perspective is thus easily acquired; and as they have not to trust to their imagination, either in sketching or shading, they speedily acquire considerable accuracy in delineating objects, and to an extent far greater than would be at first supposed.

Our remarks on aberration † will prepare the intelligent reader to expect that there will be considerable error in all the external parts of the picture. This may be avoided by employing a lens of the meniscus form, in place of a convex one. It is, however, more expensive, and less easily obtained than a double convex one.

A very ingenious application of the camera, on a large scale, is often employed for the purpose of obtaining, on a level surface, extensive views of distant scenery; and some of these answer the purpose extremely well. One of the best we have yet seen is that of the observatory and museum of Dumfries, in Scotland. By it, views extending over a radius of ten or more miles are accurately represented on the receiving-surface of the table. One of these arrangements is represented in Fig. 35.

Fig. 35.

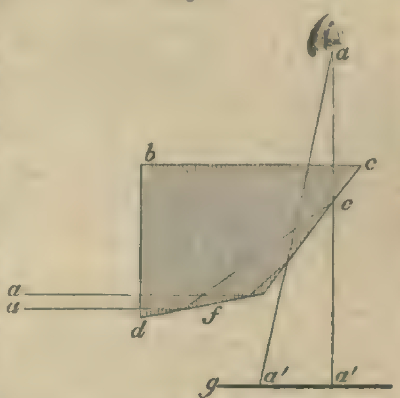


The arrangement is very different to the simple camera we have just described. In Fig. 35, *a* represents a reflector, on which the distant view is first received; the light is thence transmitted through the lens *b*, and at last received on a table covered evenly with white paper, as at *c*. The spectators should be placed, with the table, in a room or tent from which all light is excluded but that which passes through the lens. An arrangement of this sort can be easily fitted in the roof of an attic; and if the reflector be made so as that it can be turned round in any direction, or the angle of its elevation altered, the spectators may have either a view of distant or proximate objects in any direction around them.

This form of the camera is highly applicable to the purposes of the artist; and if the lenses and arrangements are carefully fitted, the picture produced on the paper screen is of great beauty and accuracy. As an illustration of this, we may observe, that by means of the camera to which we have already alluded, we were enabled to trace the ridges of hills and the windings of a very distant river, in a far more distinct manner than the painter or sketcher ever attempts to delineate them either on canvas or paper.

The camera lucida, which consists of a four-sided glass prism, is a very ingenious and simple contrivance, which may also be used by artists for sketching purposes. One of these is represented in the succeeding cut.

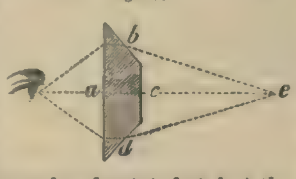
Fig. 36.



In Fig. 36, *a a*, *a' a'*, represent the direction of the rays proceeding from an object, and their subsequent reflection both to the eye and, apparently, to a piece of paper placed beneath the instrument; *b c* and *b d* are two sides of the glass prism; the angle *c b d* being a right angle. The other two faces of the glass are cut at different angles; *e* being at one of 135°, and *f* at an angle of 67½°. The rays *a a* first fall on the face *f*, and being thence reflected to *e*, reach the eye, which seems to observe their image on the sheet of paper, *g*, placed beneath the prism. The spectator, looking through the glass, is thus enabled to sketch an image on a surface placed parallel to the rays of light proceeding from the object. On careful inspection, the reader will perceive some similarity to the camera obscura which we previously described—the eye, in fact, receiving the rays as did the ground-glass plate.

We shall here include a description of a well-known optical toy, called the *Multiplying Glass*. It has one flat surface, on the other side of which numerous facets or planes are cut. It may be described as a plano-convex lens, whose curved surface is formed of a variety of planes; and, like that instrument, the multiplying glass produces its effects by the refraction of the rays of light incident on one of its surfaces. Fig. 37 represents one of these arrangements with three planes. *a* represents the flat or entire plane surface of the glass, and *b c d* three planes cut on the opposite surface. If a ray of light pass from an object *e* to the eye of the spectator, through *a c*, it will not undergo refraction, for reasons already stated;‡ but the rays *e b* and *e d*, falling obliquely on the planes *b* and *d*, will suffer refraction, and will be therefore viewed at a different angle by the eye than that which passes perpendicularly through, as at *a c e*. Of course, the same reasoning applies to any number of facets cut on the glass; and as the number of these will increase the number of angles under which one object will appear to the eye of the observer, so the appearance of the object will be proportionably multiplied.

Fig. 37.



THE MAGIC LANTERN, PHANTASMAGORIA, DISSOLVING VIEWS, CHROMOTROPES, AND PHYSIOSCOPE.

THERE are few optical instruments which are of so amusing a character as those named at the head of this section; and as they are all constructed on similar principles, we have deemed it desirable to treat on them collectively.

---

* See *ante*, p. 47.

† *Ante*, p. 44.

‡ See *ante*, p. 45.

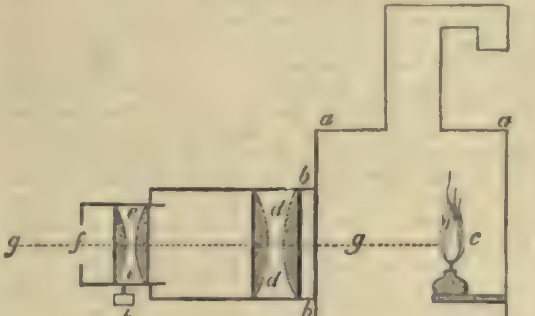
In all, except the physioscope, the object is strongly illuminated by light from a lamp or other arrangement, and the rays passing *through* the picture are subsequently magnified, and the image received on a white screen. In the physioscope, the rays *reflected* from the object are magnified, and their image received in a similar manner.

Commencing with the magic lantern, with whose pretty effects we are all so well acquainted, we may remark, that those sold for the amusement of young persons, are constructed on exactly the same principles as the dissolving views employed in the larger arrangements of public institutions; and, indeed, only differ in their size and quality of workmanship.

The best form of an ordinary magic lantern is that of two sets of lenses, each of which generally consists of two plano-convex lenses. The larger of these two sets is placed nearest the source of light; and is called the condenser. This receives and condenses the light, which then passes through the painted glass or other object; and is afterwards transmitted to the next set, whose object is to magnify the rays so travelling. The relative distance between the two sets of lenses can easily be altered; because, whilst the condenser is fixed, the magnifying glasses are easily moved to and fro in a tube by means of rack-work; or, being in a tube which fits tightly in that holding the condenser, they are easily shifted by the fingers. This operation is called "focussing;" and on care, in this respect, depends the accuracy of outline of the picture on the screen.

We need scarcely say, that unless the axis or line passing from each lens proceeds through each exactly in their centres, the instrument will not give successful results. The source of light must be so placed, that its most brilliant portion is also in the same straight line. In other words, a horizontal line passing from the centre of the light to the outer lens, must pass exactly through the centre of all the lenses. The following engraving illustrates the section of a magic lantern of the most improved form.

Fig. 38.



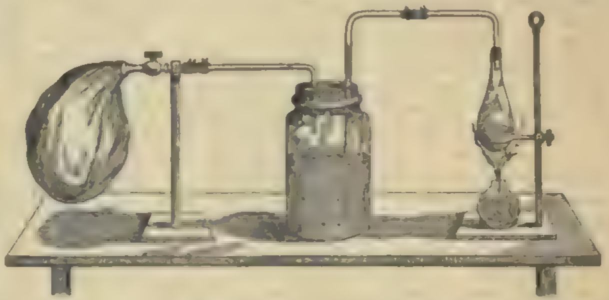
In Fig. 38, *a a* represents the box of the lantern; *b*, the groove in which the painted slides are placed; *c*, the source of light; *d*, the condensing lenses; *e*, the magnifying lenses; *f*, a stop to cut off the superfluous rays, which would diminish the brightness of the picture; *g g* represents an imaginary straight line, passing through the centre of the light and of all the lenses; *h* is a nut, by which the lenses are properly focussed. In purchasing this instrument, care should be taken that all the lenses are free from streaks or hollow specks, as these mar considerably the good effect of the picture on the screen. In occasionally using the electric light, we have observed, that the light passing from bad lenses presents almost a mass of lines of shadow. The worst glasses, however, rarely show this to any great extent on the screen when ordinary artificial light is employed.

Everything depends on a good strong light being employed to illuminate the objects exhibited in any of the arrangements to which we are now referring; and this, therefore, demands our attention before we proceed to describe their separate details.

For instruments of a small size, an oil lamp, or gas flame may be employed; but when large arrangements are used, the oxy-calcium, oxy-hydrogen, or electric light becomes necessary.

The oxy-calcium light is a very simple and useful contrivance; by means of which, considerable illuminating power may be obtained. It depends on the fact, that almost any flame, on being urged by a jet of pure oxygen gas on to a piece of burnt lime, will produce an intensely white light. Various arrangements are sold by the instrument-makers for this purpose. The oxygen is produced from chlorate of potass mixed with half its weight of black oxide of manganese. The mixture is placed in a glass retort, to the stem of which an india-rubber tube is attached, connecting the retort with a gas-bag or bladder. On applying heat to the mixture, by means of a spirit or gas lamp, abundance of pure oxygen is afforded; which passing into the bag, soon fills it. It is advisable to allow the gas to run through some water in a bottle, so as to prevent the passage of injurious substances, which may injure both the brass connections and the texture of the bag itself. The following engraving illustrates an apparatus of this kind; which we adopt ourselves for making oxygen on a small scale, and for filling a bladder.

Fig. 39.

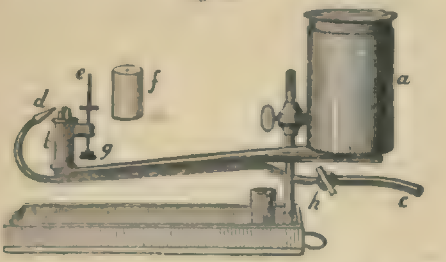


This arrangement is thus constructed and managed. After tying a bladder to a stopcock, drive out all the air it contains by gentle pressure, and leave it moist. Then tie to the end of the stopcock a piece of india-rubber tubing about two inches long. Into a wide-mouth bottle holding about a pint of water fit a cork which has had two holes bored through it, just large enough to receive two pieces of pewter gas-pipe. One of these must reach to the bottom of the bottle, and the other should just pass into its inside through the cork. The bottle, which we will call the purifier, should then be three parts filled with water; and having the retort or flask ready for making oxygen, attach its stem, by means of another piece of india-rubber pipe, to the pewter tube which reaches to the *bottom* of the bottle. The *short pipe* is to be attached to the *stopcock* of the bladder. On the right we have the Florence flask, in which the oxygen mixture is contained; in the centre the purifier, whose object is to retain any manganese or chlorine which may pass over; and, on the left, the bladder is observed in the process of filling. After all is prepared run a little melted cobbler's wax over the cork of the bottle, to keep it air tight; then open the stopcock of the bladder. On lighting the spirit-lamp, the gas will pass from the retort through the water in the bottle, and, proceeding through the stopcock, will gradually fill the bladder; as soon as this is filled, remove the retort before taking the spirit-lamp away, lest the water might pass into it and destroy it. The above is a very simple and yet effective arrangement; and its cost is trifling.

Having thus obtained a supply of oxygen, the next point of importance is its application to the required purpose; and for this, a blowpipe and a lamp of some kind are requisite. Almost every optical instrument-maker manufactures these in what we may call a special form. We shall therefore, we trust, be not considered as making an invidious selection, if we state, that as a matter of choice we prefer that illustrated in the annexed engraving; which is made and sold by Mr. J. J. Griffin, of Bunhill-row, London.

In Fig. 40, *a* represents the spirit-holder; *b* is the wick-holder, in which there are three tubes for separate wicks; *c* is the tube which brings oxygen gas from the gas-bag, the supply of the gas being regulated by the stopcock *h*; *d* is the jet by which the gas is directed into the flame of the spirit-lamp, the wicks of which must be so arranged that the gas does not strike upon the cotton and produce a ragged flame, to which end the wicks must be carefully spread on the two sides; *e* is a wire for supporting the lime cylinder, which is shown apart by *f*; and *g* is a milled head for turning the cylinder, so as to present different sides of it to the action of the flame. The front end of the apparatus is put bodily into the lantern, through an opening made for that purpose in the back of the lantern. The cylinders of lime, fixed at *e*, may easily be made by filing a piece of hard fresh-burnt lime into a cylindrical form; they may be about an inch long, and half an inch in diameter. In using this arrangement the spirit-lamp is first lit, and the lime brought into its flame. This drives off the moisture which the lime always contains; and which would cause it to split into pieces if it were suddenly heated. The stopcock, *h*, is then opened, and oxygen gas is allowed to pass through the jet *d*, so as to force the flame on the lime cylinder. Weights should be placed on a board covering the gas-bag or bladder, which may lay on the floor, and be connected with *c* by means of an india-rubber tube. A most beautiful white light will be thus obtained, which gives the excellent results when applied to the magic lantern and similar arrangements. Of course, the light may be kept up for any length of time, by maintaining the supply of gas through the jet, and of spirit in the lamp. The lime cylinder should be continually turned round, so as to prevent it burning into holes, which would speedily lessen the amount of light; and sometimes might throw back the flame, and crack the glasses of the condenser.

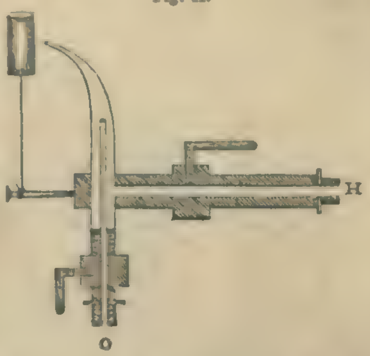
Fig. 40.



In using the oxy-calcium light no danger of any kind can arise; and as such, it is eminently fit for home use. This cannot be said of the next arrangement; which should never be employed except by those well acquainted with the risks which are incurred. Despite an experience of some years, and although from such we naturally have become careful during its employment, we have had several accidents with the oxy-hydrogen arrangement, which might have proved serious; and which, if occurring to inexperienced persons, would have possibly ended in fatal results. The force of our remarks will be appreciated as the student peruses the following description of this apparatus.

The oxy-hydrogen, or lime light, is always employed when large dissolving-view lanterns are used; and whilst not so powerful or so pure as the electric light, it has the advantages of constancy, steadiness, and greater convenience of application. An intensely hot flame is produced by the combustion of hydrogen or coal gas, together with oxygen gas; and for this purpose a peculiar form of blowpipe is required, whose object is to keep the two gases separate until the moment of their combustion. If this be successfully done, all danger will be obviated: in the absence, however, of this precaution, the most dangerous explosion will certainly ensue. We shall not enter into a description of various kinds of these blowpipes, but at once recommend that which we prefer for our own use. (See Fig. 41).

Fig. 41.



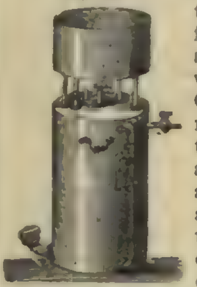
In the annexed engraving, H represents the passage by means of which the hydrogen or coal gas enters the blowpipe, and passing on, it at last escapes at the jet. O shows the opening by which the oxygen gas enters a pipe, which is entirely isolated from the hydrogen compartment until the two gases mix at the small orifice at the top of the oxygen tube; and this being near the mouth of the jet, prevents any previous admixture of the two gases. Stopcocks are attached to each tube to regulate the supply of the gases, and the cylinder of lime is placed in front of the jet, as represented above. The lime cylinder is almost always mounted on a pin connected with clock-work, which, by its rotation, causes different surfaces of the cylinder to be successively presented to the jet.

In using the blowpipe, the following directions should be carefully attended to, both as regards questions of safety and success:—1st. To fill the bags with gases. The oxygen bag may be filled as already described, for the oxy-calcium light. Care should be taken always to use the same bag for the same gas; and never to employ the bag containing hydrogen left from a previous exhibition if a few hours have elapsed, lest any air may have entered, and have so formed a dangerous and explosive mixture. The student should always remember, that both bladders and india-rubber bags are porous; and that gases have an astonishing tendency to mix together, by what is called endosomic action. Coal gas is best employed, as being easily obtained; and the bag may be filled by connecting it with an ordinary gas-pipe. Before doing this the bag should be completely emptied of air, by rolling it up and pressing it. It may then be left to expand by itself, through the pressure of the incoming gas. Pure hydrogen may be used; and is produced by adding one part of strong sulphuric acid to six parts of water, which, when cool, should be poured on zinc cuttings, or iron nails, contained in a stoneware or leaden bottle. Water is thus decomposed, and its hydrogen set free. The gas should be allowed to pass through a bottle of water, to purify it,[*] before being received in the bag. This will prevent corrosion of the brass and other metal parts of the stopcocks and blowpipe. —2nd. In attaching the bags by the india-rubber pipes to the blowpipe, care should be taken that each should be affixed to the proper connection. The hydrogen should pass through that tube which surrounds the inner one supplying oxygen; this is a matter of great importance. Care should also be taken to have all the connections perfectly air-tight, or loss of gas, and risk of explosion may occur.—3rd. The hydrogen stopcock being opened, the gas should be lit, and allowed to burn gently on the lime cylinder till it is quite dry.—4th. When this is done, the light may be produced by the hydrogen cock being first turned on full. The oxygen cock may then be opened, and afterwards the supply of hydrogen diminished, until a full, brilliant, and white light is obtained. The operator should always make it a rule to turn on the *hydrogen* tap fully first, when *producing* the light; and to turn off the *oxygen tap first* when he desires to extinguish the light. It is also a safe precaution always to have a little excess of hydrogen over the oxygen supply. This slightly lessens the light, but adds to the safety of the arrangement.—5th. When india-rubber bags are employed, the weights pressing each should be equal on both bags. This will ensure a uniformity of supply. In large institutions, gasometers or gas-holders are always used, and these are sometimes of considerable size. They are, however, unfitted for private use, for which nothing is better than the bags to which we have alluded.

---

[*] See *ante*, p. 61, Fig. 39.

Fig. 42.



In Fig. 42, a very convenient form for a small gas-holder is illustrated. It consists of a trough to hold a supply of water, from which runs a pipe fitted with a stopcock, into the bottom cylinder which is intended to contain the gas. On the right-hand side is a cock, by means of which the gas passes when the holder is in use. When such an arrangement is to be filled with gas, all the cocks are first to be opened, and water must be poured into the trough. This will run into the cylinder and fill it. Each cock is then closed, and a screw, observed at the left hand of the lower part of the holder, is removed. If the vessel be quite air-tight, only a few drops of water will escape. Into the opening thus made, the end of a retort from which oxygen is being made, is introduced, so that the gas may pass into the holder. The water will escape as the gas passes in, and it is therefore advisable to place the vessel over a tub during the process of filling. Of course, two gas-holders will be required for the purposes we have referred to—one for oxygen, and another for hydrogen. The latter is filled by passing in the tube from the hydrogen bottle; or, if coal gas be used, an india-rubber pipe may be attached to the stopcock on the side, the other end being connected with an ordinary gas jet. The holder must first be filled with water, and the lower screw afterwards removed, as when filling with oxygen.

In public institutions, where large gas-holders are used, a sufficient quantity of gas is prepared to last for a few days; and the slight admixture of air, through accidental leakage or otherwise, which always occurs, is a matter neither of importance or of danger. In using small holders, such should be first entirely emptied of all gas by means of water, and then they may be refilled at as short a time as possible before their contents are required for use: an equality of pressure should also be maintained in each, so that the gases shall pass from their respective vessels at an equal speed and pressure. A stock of lime cylinders may easily be made by means of a file and some good hard lime; and that obtained from Ireland is best for the purpose. The cylinders, which may average an inch and a-half in height, and three-quarters in diameter, should have a hole pierced half-way, or wholly through them, to permit of their resting on the wire-holder which sustains them before the jet; and until required for use, they must be kept wrapt up in paper, and in a glass-stoppered or tightly corked bottle, to prevent access of moisture, which would speedily destroy them. As they are of next to no cost if made at home, a fresh one should be used on each occasion. If purchased of the optician, they become rather an expensive affair; and yet these have no advantage, in any respect, beyond such as may be made by any person in the manner we have explained.

Having thus given sufficient directions respecting the management of the light, we proceed to speak of the cleaning and general care of the lenses.

Most persons attempting to show views by means of any of the instruments to which we are now directing attention, have to experience the annoyance of finding the lenses covered with moisture at certain seasons of the year—a circumstance which almost entirely prevents the appearance of the picture on the screen. This partly arises from the vapour evolved by the combustion of the materials from which the light is produced; indeed, water is formed in abundance when an oil or gas flame, and the lime light, are employed. This evil is, however, easily remedied by having the light lit for some time before the exhibition takes place; and, in the case of the lime light, by allowing the hydrogen to burn gently against the lime cylinder, and thus drying it also at the same time. In every case the lenses should always be a little warmer than the air of the apartment; and thus, of course, all chance of the condensation of moisture is at once removed. It is a good plan to cover the whole of the lantern by means of a thick sheet of baize, so as to prevent the deposition of dust or dirt on the lenses when they are not in use.

The lime light causes a considerable quantity of volatised lime to settle on the lenses, and soon dims their surface. This requires that they should be frequently cleaned. Unless care is taken in this operation, the polished surfaces soon become scratched, and of course are so far deteriorated. The plan we have always adopted, is that of first removing all the lenses from their seats, and wiping each perfectly with a damp old linen towel, to take off the "rough coat" of dirt. Each lens should then be carefully washed, by means of cotton wool, with spirits of wine (not methylated spirits, because these contain a resin in solution), and afterwards it may be polished with a soft chamois leather, or what is still better, an old silk handkerchief. No polishing powder, or anything of a solid nature should be used, because these almost invariably contain gritty hard matter, which soon spoils the glass. The towels should be kept in a place where no dust or dirt can settle on them. Almost every one has an idea that nothing is more difficult than to scratch glass; but chemists, opticians, and photographers know, to their cost, that the difficulty lies in preventing, rather than in producing, that result. The lanterns should afterwards be well cleansed from all dust, both inside and out; and the lenses may then be replaced in the exact position which they had previously occupied. The slides or views should also be kept scrupulously clean, or ugly black spots of dust may appear on the screen; and when not in use they should be kept in racked shelves, or in boxes in which they may be kept separate, and thus any risk of fracture be avoided.

We have thus given minute directions in reference to the general management of the magic lantern, &c.; and may here remark, that the only difference between it and the phantasmagoria, is, that the former is so used as to show the pictures on the same side of the screen as the spectators are placed; whilst, in the latter, the views are cast on a transparent screen, and the lantern is on the side opposite to the position of the spectators. By this arrangement the size of views is *diminished* by bringing the lantern nearer to the screen; and *increased* by removing it therefrom. This is an advantage when the instrument is employed to amaze young folks, who are greatly puzzled to know where the views come from; and also at the sight of the figures apparently retreating or advancing. An opaque screen or thick linen sheet is best for the magic lantern; whilst a thin calico sheet, moistened with water, answers best for the exhibition of the phantasmagoria. In either case the screen should be kept tightly stretched at each side, and at the corners, and should be in such a position that draughts of air may not cause it to swing to and fro.

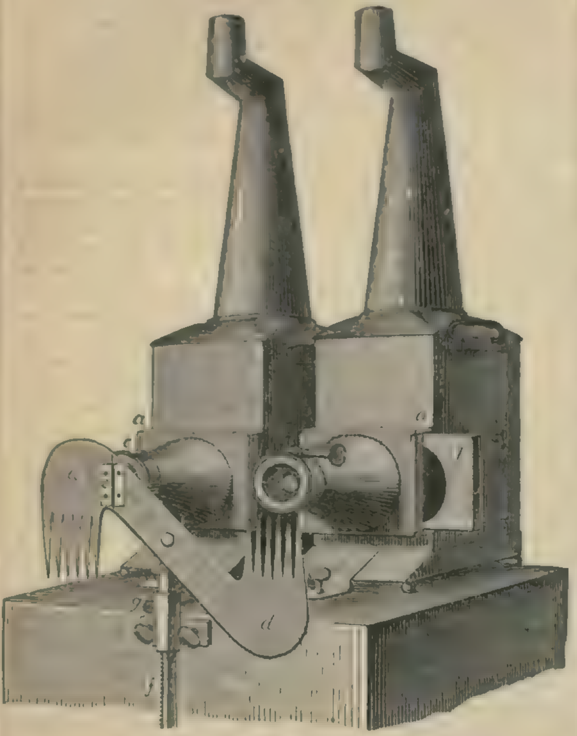
DISSOLVING VIEWS, AND CHROMOTROPES.

At one time the exhibition of dissolving views was confined to the London Polytechnic Institution; and they have invariably proved a most interesting and instructive addition to entertainments uniting science and amusement.

Two magic lanterns placed side by side, and throwing an equal-sized picture on the screen, are the apparatus required. There are additions, which we proceed to describe, by means of which the "dissolving" effect is produced. All our previous remarks on the magic lantern are therefore equally applicable to this arrangement in every other respect. The following engraving illustrates a very usual form of the dissolving view apparatus.

In Fig. 43, letter *a* represents the slider-holder; *b* is a slider partly inserted into the holder; c is part of the rack-work for adjusting the lens to the picture. The adjustment is regulated by the appearance of the picture on the screen. *d d* is the *dissolving apparatus;* that is to say, the apparatus for making one picture gradually disappear while another gradually comes into view before the spectators. This change of pictures is managed thus:—The bar *f*, which is attached to the screen *d e d*, ascends and descends in a collar; this is screwed to the front of the box on which the apparatus is mounted. It is provided with a rack, which is acted on by a pinion marked *g*, and the pinion is turned by a handle. Supposing the pair of lanterns to be in action, and each lantern to contain a slider, one of these sliders will give a picture upon the white screen, while the other is stopped by the upper limb of the screen *d*. If, then, the screen *d e d* is gradually raised, by the turning of the handle *h*, which causes the racked bar *f* to ascend, the acting slider will be gradually covered by the rising comb of one end of the dissolver, while the other will, in the same proportion, become uncovered by the rising comb of the other end of the dissolver; so that, when the first picture is quite obscured, the second will be quite developed. In that manner, the first picture is made to dissolve or gradually fade into the second picture. At *e*, in Fig. 43, the dissolving screen, *d d*, has a hinge, the use of which is to admit of suddenly cutting off the action of the picture in the corresponding lantern. This action is required for the exhibition of *lightning* and other *sudden effects*. The change of sliders in the lanterns is made when each nozzle is alternately obscured. The turning of the rack-work, by which the dissolving is effected, must be slow, regular, and noiseless.

Fig. 43.

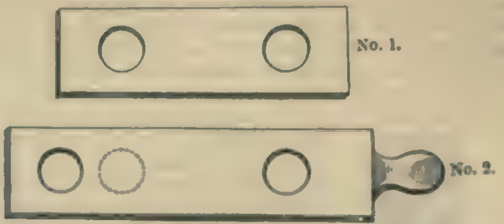


We have here given the plan usually employed in the dissolving-view lanterns. We, however, will give another one, which we used ourselves in the lanterns of the Glasgow Polytechnic, which is extremely simple in its construction. (See Fig. 44).

No. 1 is a piece of wood with holes, which are placed exactly opposite to the ends of the lantern lenses.

No. 2 is a slip of wood made to slide at the back of No. 1, also having holes, but in different positions. It is evident that only one of the holes, as cut in this, can be open at the same time with those of No. 1. Thus those on the right hand are open; but supposing that the slip is moved to the right hand, then the right hole will be closed, and the left one opened. Thus by sliding No. 2 to and fro at the back of No. 1, the views are dissolved.

Fig. 44.



This arrangement is an exceedingly useful and effective one; and any person having a pair of lanterns, can easily arrange them as dissolving-view apparatus, by having two slips cut as illustrated in the engraving, and by fixing them in a frame in front of the nozzles of the lanterns.

In arranging the lanterns, they must be placed at a slight angle with each other, so that the light they cast on the screen shall fall equally on it. In other words, the centre of each picture, cast by each lantern, must fall on the centre of the screen: this is technically termed "centre-ing" the lanterns.

Much care is required to focus the lenses, so that a clear and distinct picture be obtained. As, however, this can only be arrived at by practice, we forbear giving special directions on the subject, except so far as to state, that the pictures should be so focussed as that their *centres* may present the best possible image on the screen.

It will be beyond our plan to give any directions in reference to painting the slides, as that belongs to the art of the glass painter. An unlimited supply, either on hire or for purchase, is kept of all kinds, whether views, astronomical diagrams, chromotropes, &c., by most opticians in our large towns. Chromotropes are simply two pictures so arranged that they may revolve over each other on a common centre; and the lines painted on the glass thus intersecting each other, produce a very pleasing optical effect.

In concluding these directions and remarks, we would mention, that the magic lantern and dissolving-view apparatus, may be made an excellent medium for the instruction of youth; and they certainly should be an adjunct to the means of communicating knowledge to every public school. We shall not, however, enlarge here on this subject, because we propose to do so when describing the construction and arrangement of the oxy-hydrogen microscope.

The physioscope is a modification of the magic lantern; but instead of the light being transmitted through the object whose image is to be represented, a powerful light is cast thereon: the reflected rays are collected by lenses, as in the magic lantern, and the magnified image is cast on the screen. The human face may thus be presented in a highly magnified state; as, indeed, any other solid object may be. The difficulties of the arrangement are, however, very great; and the comparative rarity of its use will not demand from us a more detailed account of its construction.

MICROSCOPES.

ONE of the most popular of all optical instruments is the microscope; and perhaps throughout the whole of the different applications of the laws of the refraction of light, we cannot discover one to which we are so indebted for a knowledge of the beauties and wonders of natural history, and the varied appearances of almost every kind and form of matter. We shall first describe a considerable variety of microscopes, commencing with the most simple kinds, and passing to those of a compound and achromatic form; and afterwards illustrate the arrangement of the oxy-hydrogen microscope, by which a large number of spectators are enabled to see the magnified image of an object simultaneously. With our remarks on these instruments, we propose giving instructions to the student, which will assist him in collecting, preparing, and mounting objects of all sorts; and thus we hope to make our subject complete and useful to all our readers.

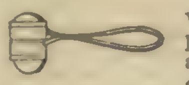
Perhaps the simplest microscopic arrangement we can mention, is that illustrated in the annexed engraving, which represents a piece of window-glass, under whose lower surface a drop of water or oil depends. The drop, of course, assumes a spherical form, and thus produces a plano-convex lens. In cases where no other kind of microscope can be procured, this is at once a ready and tolerably efficient instrument. We need scarcely remind the reader who has perused our previous remarks on lenses,* that almost any spherical and transparent substance will, as it forms a lens, answer to some extent for microscopic purposes. Even globules of melted glass may be thus employed. For fine compound instruments, lenses of precious stones, such as the diamond, have been applied. These are valuable on account of their purity, homogeneity of structure, and high powers of refraction; but through their extreme hardness they are difficult to polish, and hence are exceedingly expensive. Rock crystal, and various kinds of "paste," or glass used in making artificial gems, have been also made into lenses with varied success. The best kind of glass is almost always, however, as a rule, alone used in the manufacture of lenses for microscopic purposes.

Fig. 45.

In all ordinary spherical lenses there exists an objection to their utility, owing to the aberration of light which is a necessary consequence of their form. We have already explained the reason of this;† and to remedy it, and other evils, two very useful, simple microscopes are constructed; namely, the Stanhope and Coddington lenses.

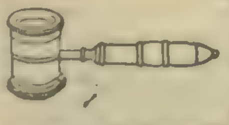
The Stanhope microscope consists of one lens, whose two curved surfaces are so ground as to have different foci, and the focal point of each terminates near the surface of the other. Hence, in using the arrangement, the object to be examined is placed on the surface of one of the ends of the lens, and is viewed through the other. This is a most useful and complete contrivance; and, in the absence of more complicated instruments, will be found of great value to the student. It is of small size, and but of slight cost; and as a field companion to the naturalist, it is of considerable advantage. Fig. 46 represents a Stanhope lens of the ordinary form, and is about half the size of the instrument itself.

Fig. 46.



The Coddington lens is an equally valuable little microscope; and its peculiarity consists in the fact, that a portion of the lens between its two curved surfaces is removed by grinding, which prevents many of the annoyances occasioned by spherical aberration. This makes the instrument of a much more complete kind than the simple lenses to which we at first referred. Fig. 47 represents a Coddington lens of about half the usual size, as sold by the instrument-makers.

Fig. 47.



Either of the above instruments may be purchased for two or three shillings; and as some of those who peruse our pages may not have the means to procure instruments of a high class, we can recommend no better microscopic arrangements for ordinary purposes. By means of the Stanhope lens the student will be enabled to examine a great variety of beautiful objects, both of an animal and vegetable nature. The structure of flowers and leaves, the wings, down, and other parts of insects, may be easily studied thereby. We know of few more interesting amusements than a morning spent in the microscopic investigation of the infinite variety of objects which the bountiful hand of Nature spreads in all directions about us. Whilst we may view, with awe and admiration, those immense results of the Creator's power which the telescope reveals to us, we can, by means of the sister instrument, the microscope, dive into the minutiæ of Creation, and reap an immense amount of intellectual pleasure therefrom.

Having drawn attention to some of the best kinds of simple microscopes, we shall now pass on to consider the construction and uses of those called "compound," in which an extensive power of examining the most minute objects is afforded by means of a combination of lenses, and other apparatus.

COMPOUND MICROSCOPES.

From the remarks which we have made in our previous pages, when speaking of lenses, the reader will have observed that the magnifying power of a lens is inversely as its focal length; or, more plainly, the shorter the focal length, the greater is the magnifying power of the lens employed. It would follow, therefore, theoretically, that a single lens may be manufactured which would afford any magnifying power which might be desired. In practice, however, this is impossible; because, when the focal length of a lens is exceedingly small, the eye, lens, and object would require to be so near each other for the purposes of microscopic investigation, as to entirely prevent every chance of the observer using such an arrangement.

Lenses of almost the shortest possible focal length may, however, readily be employed, when combined with another lens which magnifies the image produced by the former. Such is the combination found in the compound microscope, in which the *object-glass*, or lens of short focal length, receives the rays passing from the object under examination, and produces an image thereof; such image is viewed by means of another lens of far less magnifying power, and therefore of greater focal length, which, being next the eye of the observer, is called the *eye-glass*.

By such an arrangement an extended field of view is obtained, and the magnifying power which may be employed is only limited, practically, by the skill of the instrument-maker.

We must, however, remind the reader, that if ordinary glass lenses are employed, all the effects of chromatic and spherical aberration (of which we have already spoken so frequently) are called into play; and hence all the rays except those passing nearest to the centre of the lenses of the instrument must be cut off by means of stops, which of course would cause a great loss of light. This difficulty has, however, been remedied in another way, by using achromatic lenses; and such instruments as the compound achromatic microscopes, manufactured by Ross, Smith and Beck, and other eminent makers, are perhaps amongst the most perfect productions of human skill and ingenuity.

It, of course, will be out of our power to recommend the best form of microscope for the student, varying as they do in so many particulars. As, however, the means of many of our readers may not permit the purchase of a high-priced instrument, we may state, that for ordinary purposes, a good microscope, containing most of the modern improvements, may be obtained for from three to five pounds, from the maker. And sometimes, at sales by auction, a very good instrument may be purchased at a comparatively low cost. In such cases, however, the purchaser should not trust to his own judgment, if inexperienced, but should first have the arrangement examined by an optician, so as to prevent disappointment. We may state, that in nearly all our large towns, philosophical instruments are made expressly for public sales, at which both the article and the purchaser are frequently "sold" together. As an instance of this, we may mention the case of a friend who purchased, in one of the large towns in Scotland, what he thought to be a first-rate galvanic coil machine. On attempting to obtain a shock from it in the usual manner, he discovered, that instead of the machine containing 300 or 400 yards of covered copper wire, there were only a few inches connecting highly-polished brass binding-screws; the remainder of the apparatus being what is technically called a "dummy."

---

* See *ante*, p. 46, *et seq.*

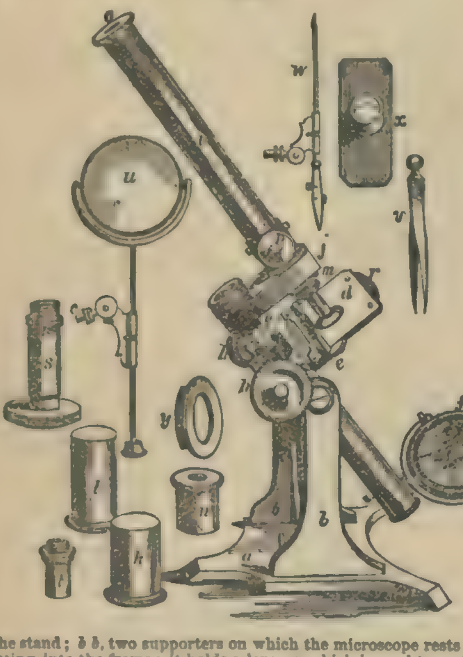
† *Ante* p. 44.

As we cannot properly recommend any particular form of microscope, or the production of individual makers, consistently with fairness to all—we have, therefore, an equal difficulty in presenting an illustration of one of the most approved kind.

That represented in the annexed engraving will, however, give a general idea of the most essential parts of compound microscopes, and will also assist the tyro in putting any of the ordinary class of instruments together. In almost every instance the essential parts are similarly constructed by the different makers, the improvements or special characteristics being generally connected with comparatively minor details of the instrument.

In Fig. 48 we have an illustration of an excellent form of compound microscope.

Fig. 48.



a, the stand; *b b*, two supporters on which the microscope rests; *c*, a peg fitting into the frame; it holds a lens, *u*, which is used to cast light on opaque objects; *d e*, the stage on which the object is placed; *f*, a mirror which throws light through transparent objects; *g*, a rack-work for raising and lowering the tube *l*; *h h*, two thumb-screws for adjusting the focus; *i*, a branch on which the tube *l* is fixed; *l*, the brass tube holding the eye-piece, *o*.—The other parts here represented will be more fully described as we proceed.

We may now refer to certain modifications of detail, which cause some instruments to be highly valued by microscopists; and for this purpose we commence with the lower part of the microscope. The use of the mirror, *f*, is to illuminate objects placed on the stage, *d e*. In this stage is a circular hole, through which the light reflected from *f* passes. Of course the reflector is employed only for transparent objects. During day-time, the mirror should be so placed as to reflect as much light as possible to the stage, and this is best effected by exposing the reflector to daylight at a window. At night-time, an argand, oil, or gas-lamp may be employed, the light of which should be shaded by means of a chimney-glass, of a very light-blue colour. This corrects the yellow colour of artificial light, and so renders it whiter than it otherwise would be. The mirror is so fixed to the arm which supports it as to allow of its being placed at any favourable angle with the stage, and thus to secure at all times sufficient reflected light.

A very ingenious arrangement has been proposed, in which a piece of pure white unglazed stone or ceramic ware is employed as a reflector. Such an arrangement prevents that unpleasant glare which light reflected from a polished surface generally has. The ordinary reflector may easily be converted into one of these by covering the surface of the glass with any white powder, of which, perhaps, sulphate of lime (plaster of Paris) is the best.

The stage, *d*, on which the object rests, is of considerable importance in the microscope. It is generally made in two parts, which easily and yet firmly slide on each other. By means of these combined motions, the objects placed thereon can be readily shifted to and fro, so as to be in any required position with the object-glass. An accurate and readily shifting stage is of great use when high powers are employed. Its motions are generally guided by means of a small lever, working in a universal joint; various arrangements, however, are employed by different makers.

On one side of the stage is fixed, by means of a peg, *c*, a lens, represented at *u*, in Fig. 48, whose object is to illumine opaque bodies whilst under examination, and for which the mirror would be useless. The focal point of the lens is brought to bear on the object, so as to afford as much light as possible. The student, however, must not employ the direct solar rays for the purpose; for not only will the light be too powerful, but it is more than probable that the heat so concentrated would immediately destroy the object, if of an organic nature. Next, above the stage, and screwed into the long brass tube, *l*, is the object-glass, by which the rays passing from the object are first received, and subsequently transmitted, by means of the eye-piece, to the eye of the observer. Several of these, having different focal lengths, are supplied with the compound microscope; and, as we have already intimated, it is essential that such should be achromatic. The image formed by the object-glass is viewed by means of the eye-piece, *o*, of which two or three are generally provided, each having different magnifying powers. By means of the latter, the image afforded by the object-glass is magnified and presented to the eye.

Arrangements are required for focussing the lenses; or, in other words, to enable them to present the best possible image to the eye of the observer, by regulating their mutual distance. This is generally done by means of two sets of screws and a rack-work motion; the latter of which is represented at *g* in Fig. 48, the thumb-screw being seen at *h*. This is what we may call the coarse adjustment, which is still further improved by means of a similar but much finer arrangement represented at *p*. On the exactness of adjustment of the lenses, and their distance from the object under examination, depends the excellence of the image as seen by the observer.

Objects may be mounted, if intended to be preserved, under thin squares of glass, secured at their edges by means of pasted paper. The mode of doing this is described under the head of "Oxy-hydrogen Microscope," &c. Many objects may, however, be temporarily placed in the microscope by means of pincers or forceps, respectively illustrated at *v* and *w*. It is often necessary to examine water insects in a living state, and for this purpose a trough containing the liquid must be used: of this kind one is represented at *x*.

We have thus endeavoured to illustrate, for the use of the student and our readers generally, the chief parts of modern compound microscopes. Some excellent works have been published on the subject, in which all details are fully treated; and, perhaps, the best that we can recommend for those of our readers who are disposed to enter fully into microscopic investigation, is that by Dr. Carpenter, entitled *The Microscope and its Revelations*; in which the subject is almost exhausted. Other valuable treatises, of a more elementary character, such as *Half-hours with the Microscope*, and similar productions, form excellent hand-books to the student.

We may here describe a very simple form of microscope, which can be frequently employed in the stead of larger instruments; and it can be purchased of most optical instrument-makers for a moderate cost.

Fig. 49 represents one of these. Its principal parts

Optics.

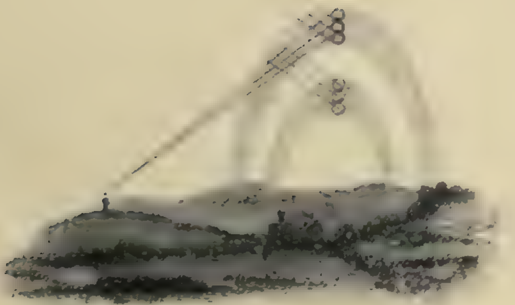
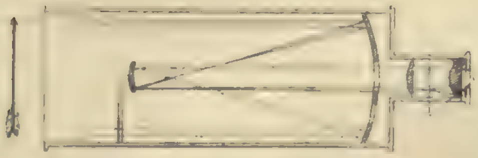
The Solar Microscope. See Page 69.

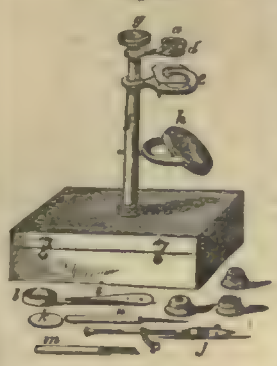


Cause of the Rain-bow. See Page 50.



The Gregorian Telescope. See Page 71.

Fig. 49.



are—*a*, the magnifying lens; *e*, the frame on which the objects are supported; *f*, an upright stand; *g*, a regulating screw; *h*, a mirror casting light through transparent objects. The other parts in Fig. 49 represent lenses of different magnifying powers, which are fixed in the holder, *d*; and forceps, &c., for holding the objects to be examined. In observing an opaque object, light may be thrown upon it by holding a double convex lens or burning-glass, so that its focal rays shall be cast on the object, in the manner we have already mentioned. It will be observed, that this arrangement somewhat resembles the compound microscope, but differs in this respect—that the *object* is viewed by the eye through the eye-piece, which is, at the same time, the power, and not the *image*, as is the case in the compound arrangement.

THE OXY-HYDROGEN MICROSCOPE.

The oxy-hydrogen microscope is an instrument of great value when employed for the purpose of exhibiting, in a popular manner, some of the most interesting facts brought to light by means of the compound microscope. It is quite unnecessary for us to remind our readers, that the use of the latter-named instrument is necessarily confined to one person at a time. Now, the advantage accruing in the use of the oxy-hydrogen microscope, is that of permitting any number of persons to observe, at the same moment, almost any object, in a magnified state, which can become the subject of microscopical investigation. Of course there is a limit to its uses, arising from the colour, opaqueness, or other affections of the objects; but still, these being of rare occurrence, do not interfere with its general utility. The extent of magnifying power which may be employed, is only limited by the amount of light which can be obtained for the purpose of illuminating the objects; and for this, the electric and oxy-hydrogen lights afford every assistance.

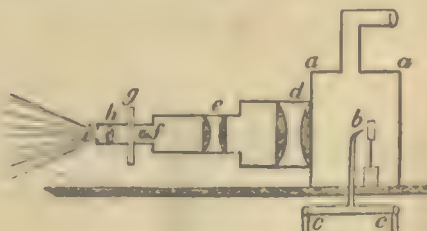
In its general construction the instrument resembles the apparatus employed for exhibiting the ordinary dissolving views; one lantern, however, only being used. Inasmuch as the magnifying power is much superior to that of the magic lantern, greater care is required in the manufacture of its lenses, and the adjustment of every part must be very exact. We may here remark, in reference to the light employed, that M. Duboscq has been very successful, so far as intensity goes, in applying the electric light for the microscope. We may, however, state, that in most cases, any advantages so gained are more than counterbalanced by the trouble and expense required to keep a galvanic battery at work; and that the lime light is decidedly to be preferred beyond any other for all practical purposes. We have already given full directions for the management both of the oxy-calcium and lime lights.* We therefore proceed to speak of the general arrangement and management of other parts of this microscope.

The lenses placed nearest to the source of light are termed the condenser; and their office, as in the magic lantern or dissolving-view arrangement, is to collect the light, and so to illuminate the object whose image is subsequently magnified. Another pair of lenses is generally placed between the "power" (that is, the last lens in front of the arrangement); and by these the light is still better concentrated on the object, which in the microscope is always of very small size, and requires strong illumination. The object is not placed, as in the magic lantern, near the condenser, but close to the focal point of the last magnifying lens; which, in future, we shall term the power. In an arrangement which the writer had constructed for the Glasgow Polytechnic (which, however, has since been destroyed by fire), the first condenser, next to the light, had a diameter of twenty-eight inches; and between it and the power, three sets of achromatic lenses, of twelve, eight, and six inches diameter respectively, were placed. By this instrument an ordinary flea was magnified so as to present a very highly illuminated image, only a portion of which covered a screen thirty-two feet square. If, therefore, the insect is supposed to be a quarter of an inch long, and an eighth of an inch broad, the superficial magnifying power, in this instance, was equal to a total of some millions beyond the natural size. Practically, we reckoned that, with a power of a quarter of an inch focal distance, the magnified result was equal, in round numbers, to five million times, superficial measurement. This microscope was the most perfect which has yet been constructed; and was an adaptation of the dissolving-view arrangement employed in the institution, of which a further account will be found under the heading "Magic Lantern," &c.

With respect to the powers employed in oxy-hydrogen microscopes, we may observe, that several should be provided, ranging from about 20,000 to 1,000,000 times or more. It must, however, be remembered, that the illumination or distinctness of the image on the screen decreases as the magnifying power is increased; and this result limits the power of the instrument. Again, unless the glasses are truly achromatic, spherical and chromatic aberration interfere seriously with the employment of high magnifying powers, and also destroy that vivid and distinct appearance so essential in microscopic illustrations. It is, above all things, essential that each lens should be *exactly* in the line of centres;† and to neglect on this point, the frequent failure of many persons in their attempts to use the instrument are due. These and other incidents occurring in manipulation, have greatly restricted the use of this interesting instrument; although, if properly managed, we know of no apparatus which can be so amusingly or more instructively employed, admitting, as it does, of a popular illustration of some of the most minute, beautiful, and complete objects of the Creative Power.

In the annexed engraving we have a section of one of the most usual forms of oxy-hydrogen microscopes. The arrangement of each part is varied by almost every maker of the instrument. Those manufactured by the British opticians are similar, in their external appearance, to the best forms of magic lanterns; indeed, the microscope is often added to a good dissolving-view arrangement, in which form it is of great value to Mechanic Institutions. The instruments made in France, by M. Duboscq and others, have all the lenses fixed to an arm of brass extending from the body of the lantern, beyond the condensers. This form is liable to derangement of the line of centres, should the brass arm receive an accidental blow.

Fig. 50.



a a, represents the box of lantern; *b*, the lime light; *c c*, the india-rubber tubes bringing the gases; *d*, the first pair of condensers; *e*, the second pair of condensers; *f*, the rack-work used for focussing; *g*, the object to be magnified; *h*, the power, or magnifying lens; *i*, a stop or diaphragm used to cut off superfluous rays.

We need give no further directions, in respect to the general management of the microscope, than those already afforded in respect to dissolving views, &c.* In cleaning the lenses, great care should be observed in replacing them exactly in their proper position in reference to each other, and in the seat or frame. It is a good plan to introduce a small piece of thin paper round the rim of each lens, so that if the lantern be accidentally shaken the lens shall not be shifted.

---

* See *ante*, p. 62.

† See *ante*, p. 61.

With respect to the objects which may be used, we may remark, that those that can be examined by the compound microscope, are equally available for the oxy-hydrogen instrument. It must be remembered, however, that the objects are inverted thereby; and, to be viewed in their ordinary appearance, must be introduced, into the slide which receives them, in an inverted condition.

As our pages may fall into the hands of managers and others connected with public societies, we shall suggest a few matters which, unless they have been previously seen, might not be thought of. Amongst these, the following form extremely interesting applications of the powers of the instrument.

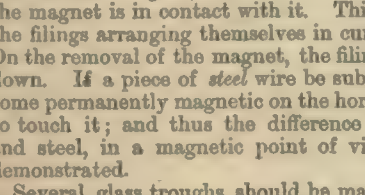
1. *The Crystallisation of Salts.*—To show this, a hot saturated solution of Epsom salts, sal-ammoniac, common salt, &c., should be kept in separate watch-glasses, close by the operator. One drop of each of these may be successively introduced on a slip of glass into the slide. The heat of the lime light will cause speedy evaporation, and the gradual and sometimes rapid formation of the crystals produces a beautiful object on the screen.

2. *Magnetic Attraction.*—This is easily exhibited by placing a few iron filings in a glass trough, such as we shall presently describe, and introducing amongst them a piece of *soft iron* wire, whose end should hang outside the trough. If this be occasionally touched by means of a horse-shoe magnet, it will become magnetic so long as the magnet is in contact with it. This will be shown by the filings arranging themselves in curves on its surface. On the removal of the magnet, the filings will at once fall down. If a piece of *steel* wire be substituted, it will become permanently magnetic on the horse-shoe being made to touch it; and thus the difference between soft iron and steel, in a magnetic point of view, may easily be demonstrated.

Several glass troughs should be made for this and the following purposes. These are easily constructed by cementing two pieces of thin, clear window-glass on each side of a frame of wood left open at the top. One of these is represented in the next engraving (Fig. 51), in which *a a a* are the wooden sides and bottom; *b b*, the pieces of window-glass; and *c*, the opening of the trough into which the objects are introduced. We scarcely dare offer any cement which we can recommend as certain to keep the trough water-tight. We have used solutions of shell-lac, india-rubber, gutta-percha, wax of all kinds, white lead, &c., but have never succeeded in producing ourselves, or of obtaining from the opticians, a trough that would long hold water. However, they are so easily repaired as to make this a matter of secondary importance.

Of course, the size of the trough must depend on that of the slit in the microscope in which it is to be placed. One, two inches square, and three-eighths of an inch wide, is convenient for most purposes.

Fig. 51.

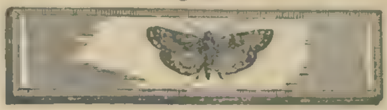


3. *Live Insects, Larvæ, &c.*—Perhaps the most amusing objects for the oxy-hydrogen microscope are found in the insects which abound in ponds, ditches, and the edges of rivers. A few of these may be placed in a trough with some water, and introduced into the slit. The insects being largely magnified, and also stimulated by the heat and light, will be observed swimming rapidly about the trough, biting, fighting, and otherwise amusing themselves. The larvæ of the water-beetle is a most beautiful object; and if two of these are introduced into the same vessel, a fierce battle generally ensues, which often ends in the destruction of one, and perhaps of both the combatants. Water-beetles, water-fleas, worms, and many other insects inhabiting the water, may thus be exhibited to great advantage; and the internal construction of their bodies, together with the circulation of the blood, may be observed at the same time. These insects are easily collected by employing a gauze net mounted on an iron ring. One of these is represented in Fig. 52.

Fig. 52.

4. *Land Insects,* in the living state, may also be shown in a trough, if the top is covered by means of a piece of card-board to prevent their escape. Dead insects may easily be mounted, by placing them between two pieces of glass whose edges are pasted together, as shown in Fig. 53.

Fig. 53.



We need not here extend our list of animated or other objects which may be exhibited, inasmuch as there are few matters to be met with in daily life, of this kind, which will be otherwise than interesting: and we shall enlarge on the subject further on.

5. *The Decomposition of Water by Galvanism.*—To exhibit this, a little zinc and mercury should be placed at the bottom of a trough, which must then be filled by some dilute sulphuric acid, and then introduced into the slit. If a piece of copper wire be dipped into the water, no gas will be given off until it touches the zinc. When this occurs, a small voltaic battery is formed, and torrents of hydrogen rise from the wire surface. On destroying the connexion between the two metals, the effect immediately ceases. By this simple arrangement the action of voltaic batteries may be readily explained.

Having thus given general hints as to the variety of uses to which the oxy-hydrogen microscope may be applied, we shall now point out two most interesting applications, which were first introduced by M. Duboscq, of Paris—namely, the exhibition of photographs, and of photographic copies of blood globules.

Photographs of landscapes, likenesses, &c., may be introduced into the slide, and magnified by a low power. It is essential that they should be transparent, and yet that the lights and shades should be very distinct. The best of this kind are those taken by the albumen process on glass plates; and of all we have yet seen, we have found none to equal those supplied from Paris. The magnified image, under a power of 20,000 times, is of the most interesting character. Some which we have tried, of a size of about two inches square, reproduced most perfectly the inscription on monuments and tombstones; whilst every crevice or crack in the stone of a building was vividly depicted on the screen.

The photographs of the blood globules of animals, &c., are of the deepest interest to the physiologist. Each living creature has a distinct blood globule for the species it represents. Hence photographs of them, when magnified by the oxy-hydrogen microscope, represent the distinctive features of the class of animal from which it has been taken, both in respect to size and shape. It is thus perfectly easy to name any animal by its blood, if a few globules are examined, and compared with what we may call standard specimens. The blood of different animals of the same order, genus, or species, may even be distinguished from each other. This interesting fact has a singular application in respect to jurisprudence; for in cases of murder, nothing is more easy than to examine, microscopically, the nature of blood-spots on the dress of the suspected person, and to be thus enabled to state definitely whether such have belonged to animals or to the deceased person. The investigations and researches of optical science have thus advanced another claim on the esteem of civilised society; and may be called in to solve doubts, which are often the cause of intense anxiety to those who, as jurymen, have to hold in their hands the balance between the life and death of a fellow-creature.

---

* See *ante*, p. 64.

Another application to which we have often applied the instrument, is that of exhibiting the effects of chemical tests, when the quantity of a substance under examination is exceedingly minute. Of course this is a matter requiring delicacy of manipulation; but a careful operator may easily show, at the same time, to any number of students, the operation of any test affording a coloured liquid or precipitate. The best mode of doing this is to brush, over a clean glass plate, a portion of the solid or liquid to be tested, and to introduce this into the slide. A drop of the test solution is then placed on the plate, and allowed gradually to run into the solid or liquid already on its surface. The characteristic colour is immediately produced. By these means we have often exhibited the mode of testing for strychnine, by the bichromate of potass, and sulphuric acid, using but a fraction of a grain of the poison for the purpose. The acid, salt, and strychnine solution were placed in three different parts of a glass plate resting in the slide; and on being stirred together by means of a glass rod, the beautiful and characteristic purple colour was at once produced; and, of course, was easily observed by all present.

In concluding our remarks on this instrument, we would strongly urge its adoption by establishments, either public or private, as an excellent means of conveying information, on an immense variety of subjects, to a large number of individuals simultaneously. By means of photographs, or by original objects, diagrams, &c., the principles of arithmetic, algebra, geometry, trigonometry, botany, crystallography, astronomy, physics, mechanics, chemistry—indeed, nearly every branch of human knowledge may be communicated. We have frequently adopted it in public for illustrating all these subjects. With respect to young persons, there exists a great advantage in its use. The whole of the illustrations must necessarily be shown in the dark; and hence there are no objects to distract or attract the attention, excepting the teacher and the image on the screen. From the latter sufficient light is always reflected to enable the speaker to watch any class, however large, and so retain order therein. We have seen numbers of the very dregs of society, and some of its choicest ornaments, equally, and as deeply interested; the former bursting from perfect quiet into enthusiasm at the wonders presented to the eye of their minds; whilst their educated and intellectual superiors have attested a refined interest as each development of the minutiæ of nature has successfully been illustrated, or exhibited before them.

THE SOLAR MICROSCOPE.

We have hitherto deferred to mention the solar microscope, as it is but seldom employed at the present time, having been, in most respects, superseded by the oxy-hydrogen arrangement.

The light of the sun is the illuminating agent, which, being reflected by a plane mirror, is transmitted through the lenses and object; the image being received on a suitable screen, in a like manner to that adopted in exhibiting dissolving views, &c. The arrangement of the lenses being in all respects similar to that of the oxy-hydrogen microscope, it will be unnecessary for us to describe more fully its different parts.

OBJECTS FOR THE MICROSCOPE.

As many of our readers may be desirous of learning the best plan of obtaining, preparing, and mounting objects for the microscope, we shall now give some general instructions, which may be of value, and assist those who are unacquainted with certain minutiæ of the *modus operandi*.

It would be impossible to enumerate the various objects which come under microscopic observation, as of course there is no limit thereto. We may, however, select some which may serve as a general type of others, and thus guide the student in many respects. In carrying out this idea, it may be perhaps as well that we take our subjects separately from the mineral, vegetable, and animal kingdoms; and we shall thereby be enabled to offer considerable variety of illustration. We may, however, remark to all our readers, that the interest of microscopic study does not consist solely in following the beaten track of previous observations. Indeed, one of the greatest charms which the microscope presents as an instrument of investigation, is the opportunity of engaging in entirely novel and independent researches by those who use it. The field it opens out is unlimited; and thus every form or kind of existent matter, whether animate or inanimate, presses into the service of the student and observer of nature.

Our aim will therefore be, to point out "how to observe," rather than "what to observe;" and in this attempt we shall endeavour to be as practical and definite as possible.

Presuming that the reader has furnished himself with a good achromatic compound instrument, we will now proceed to describe the best methods of collecting, examining, and preserving objects.

We have given special directions respecting some objects in the previous page, to which our present remarks are supplementary. Perhaps the most interesting objects of microscopic study are found amongst the insect tribe of animal life. It cannot fail to astonish every one, especially those unaccustomed to scientific observation, when they discover the extreme minuteness, and yet perfection of organs, which are noticed amongst the invisible but animate beings which exist both in the air and in water. In spring, summer, and autumn, we cannot inspire a breath of air without inhaling numbers of germs floating therein; and the refreshing draught of water taken from the river or brook, equally abounds with living creatures. Even the very dust of the ground, and of our houses, and many articles of our daily food, present living organisms, thousands, and even millions of which may be covered with a pin's point. Some of them are so small as not to exceed the twenty-thousandth of an inch in length; and yet they are provided with mouths, stomachs, &c. Their process of feeding, and their delicate organisation, may be easily detected by means of a good microscope, and the peculiarities of their construction observed, which alike puzzle the naturalist to explain, and interest the observer in their examination.

Ascending in the scale of life, we find the various parts of insect organisation to become a subject of the deepest interest; and we may state, that the same laws as to generation, reproduction, growth, and death, alike affect the existence of the smallest creatures as are found to govern the same occurrences in our own lives. Indeed, we perceive by our researches, that unity of design, simplicity of causes, and identity of effects, are alike operating on all forms of existence, modified occasionally in instances where special purposes have to be fulfilled.

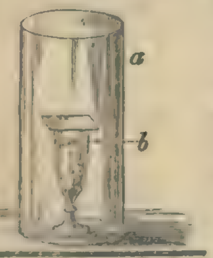
Amongst the smallest objects of insect life to which we can direct attention, are those included in the infusoria. These abound in many places, and may often be observed covering water in brooks and ditches, with an appearance resembling oil.

A stagnant pond, if examined during a hot day in spring or summer, will be found to be literally alive with insects. These should be carefully collected by dipping with a basin from the pond; and must then be transferred to a tall glass vessel, filled with water. Into this a few plants should be introduced; and those growing beneath the surface of the pond from which the insects have been withdrawn, will perhaps be the best. A little of the earth should be removed with them, and the plants will thus thrive in the vessel; and by their action on the water they will tend to keep it fresh, and fit for animal existence. Indeed, such an arrangement forms a small aquarium. By similar means we have been able to keep a good stock of insects throughout the year; and have often surprised our microscopical friends by exhibiting many curious and interesting little creatures in the depth of winter, by aid of the oxy-hydrogen microscope. Fresh water should be occasionally added; and the temperature should never be allowed to go below 60° Fah. In such a collection the student will be surprised to find an immense variety of objects. We shall speak of many of these under the head of Natural History; to which, or to any work of a similar kind, we must for the present refer our readers.

The unlimited number of land insects, places at the disposal of the microscopist a most interesting field for investigation. As it would be impossible for us to enumerate or classify such objects, we shall content ourselves by pointing out only those parts of most insects which require special notice. We must first say a few words as to catching, killing, and mounting.

Generally speaking, insects of the moth kind are best caught about dusk; and this should be done by means of a fine gauze net, similar to one already described and illustrated;* the sack, however, being larger, and of lighter materials. By this method, the wings, antennæ, &c., are uninjured. With respect to killing insects, the best plan we know of combines the advantages of producing instant death, and retaining the colours, &c., quite uninjured—which is by means of carbonic acid. In endeavouring to simplify the process of making the gas, we suggest the following plan:—Place an ale-glass in a confectioner's show-glass; and into the former put a teaspoonful of chalk or whiting. On this pour some vinegar and water, or a little hydrochloric acid, diluted with five times its bulk of cold water. On the top of the ale-glass place a small card, so as to entirely cover it. The carbonic acid will gradually escape, and, being heavy, will flow out of the ale-glass, and fill the larger vessel. Any insect dropped into the latter will instantly fall down dead to the bottom, with wings extended; and, in fact, will preserve in death every external appearance of life. The card of course prevents the insect from falling into the mixture; and none of this should be allowed to flow into the outer vessel. Fig. 54 represents this simple and effective arrangement.

Fig. 54.



a, the outer glass vessel; *b*, the ale-glass, containing the mixture producing carbonic acid gas.

The insect, if small, may then be placed between two slips of window-glass; but this should not be done until all the moisture has been dried out of the body. This is best done by leaving the insect for some days in the open air, and in sunlight. The mode of mounting, and the actual size of the glass plate, are already described.†

Considerable delicacy is required in separating the various parts of insects, such as the antennæ, eyes, wings, legs, stings, &c.; but such can only be gained by long practice, and great care. Instruments, such as forceps and small lancets, are often supplied with compound microscopes for such purposes; and whilst attempting these operations, a magnifying glass should be used, which will enable the operator to proceed with greater certainty. When the part has been removed, it should be placed on the centre of a piece-glass, half an inch wide and three inches long, and on it a drop of Canada balsam may be poured. This preserves the object from injury by shifting, &c.: the arrangement is completed by placing another slip of glass over the balsam when dry, and the edges of the two slips may then be pasted together, as already mentioned. In a similar manner, the hair, down, &c., of insects, birds, or animals; and the scales, &c., of fishes, may be preserved from injury, and placed in a fit condition for microscopic purposes.

The ova or eggs of insects are generally found in crevices or slits in wood, &c.; and from their extreme minuteness they actually require, in many instances, a microscope to discover them. Dust and dirt, so called (which, however, has been defined as "matter in the wrong place"), are often prolific with these objects. Indeed, we would venture to suggest the use of the microscope to many housewives, who might thus discover the cause of the appearance of "such swarms" of certain insects; and being so forewarned, might take the necessary steps for preventing their subsequent presence in a lively and predatory state of existence. So extremely small, indeed, are some of these ova, that they have not been seen by aid of even the most powerful microscopes. Hence has arisen the absurd theory of "spontaneous generation," an idea as discreditable to the reasoning powers of a man, as it is an evidence of the crudeness of his imagination. We need but further say here, on this subject, that if *any* creature could create itself, a Creator would be unnecessary; for, as the most minute living thing that has yet been examined, has organs which, in their construction, functions, and use, are analogous with those of the largest size of animals, it follows that the creative power should exist in every being, small or great; the result being only modified by the individual ability or strength of self-creation in each species—an argument too ridiculous to require refutation. Moreover, the advocates of the theory must admit, that inanimate matter must also have been self-creative, to be consistent in all their propositions: of this idea, however, they decline to take the responsibility; and thus they attempt to build an edifice, but forget first to lay its foundation.

An interesting class of objects is found in insects which are bred, grow, and feed in various animal substances. Amongst these we may mention the mites in cheese, the maggot, and parasitic creatures, such as the louse, the tick, &c. These are generally regarded with a degree of disgust, which, however, should not be shared in by any student of science. Duties of the most offensive kind are necessarily undertaken by those experienced in scientific pursuits, for the purposes of jurisprudence, which require the exercise of great nerve in their pursuit. The student, however, is not called to these, and may not object to examine any of the productions of nature because, under certain circumstances, these may prove offending—bearing in mind, that whatever the Deity has made is worthy of man's investigation.

Directing our attention to the organs of animals, we may mention, that a most instructive branch of inquiry is found in comparative physiology and anatomy. Commencing with the heart, we may remark, that that organ has its representative in every kind of breathing creatures. The circulation of the blood, the nervous and muscular systems, the perspiratory ducts, the skin, bone, fibre, hair, down, feathers, are mostly found in actual existence, or substituted in each order; and an intense interest is created in the search for these in different species, or the discovery of their modifications. Under the description of the oxy-hydrogen microscope and its uses, we have made special mention of the nature of blood globules, and their characteristic differences in animals; a subject of importance in a philosophical and even legal point of view.

We have thus indicated some of the interesting objects to be found in various departments of the animal kingdom, and must leave our readers to complete that which we cannot further extend without encroaching on the limits of our plan.

A very interesting field is opened out in the vegetable kingdom for microscopic study; and in it the analogies between vegetable and animal structure hold a prominent place. As we have already remarked, it will be impossible for us to give more than general hints; and the directions we have given in reference to mounting animal objects, are equally applicable to those obtained from plants, &c.

---

* See *ante*, p. 68, Fig. 52.

† *Ante*, p. 68, Fig. 53.

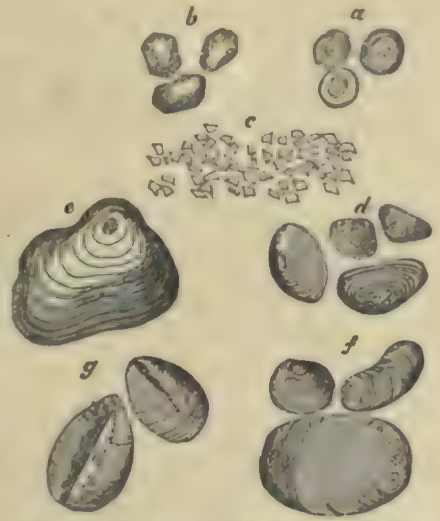
The fungi so continually formed on decayed substances vary in size, from those requiring a microscope to detect their presence, to those of the mushroom and larger kinds, with which all are familiar. Some of these present very beautiful appearances under the microscope, and are therefore well worthy of the attention of the student.

Ascending to the higher classes of vegetables, we observe the most interesting traces of analogy between plants and animals. The leaves take the place of lungs; the solid fibre that of bones; the sap is as the blood; and we might thus continue to connect the two kinds of existence by an almost continuous chain. It will be sufficient for our purpose to indicate some of the leading points of resemblance between the two kinds of vital existence; and we therefore append a synopsis of the most easily recognised subjects.

The cells of all plants perform a similar office to that of the veins of animals, as the sap—which is the blood of plants—is propagated to every part by their agency. The existence and appearance of the cells may be observed by cutting a thin slice off any branch or stem. The form of the cell, and the arrangement of the successive rings, vary in each tree; so that they are really characteristic, and form beautiful microscopic objects.

The woody fibre or solid portion of plants is, as it were, their flesh, bone, and muscle, and differs, in its physical character, in every production of the vegetable kind. Thus we have the strong and close fibre of the oak and ash, and the delicate fibres of the cotton plant. The fibrous matter of grasses is easily obtained by soaking the leaf in a little solution of carbonate of soda, and then immersing it in some very dilute sulphuric acid. Each filament will split from its neighbour, and thus may be separately examined.

Fig. 55.



a represents granules of rice starch; *b*, granules of sago starch; *c*, the granules of wheat starch; *d*, granules of potato starch; *e*, the same, but more magnified; *f*, the granules of *tous les mois* starch; *g*, is the same starch after being heated, by which the granules are burst open; *h*, is a specimen of pea starch.

The leaves of trees, &c., present a very interesting appearance, and the green matter may easily be separated from the fibre, and so produce the net-work in a separate state. There are few more beautiful objects than these for exhibition in the oxy-hydrogen microscope; and for that purpose the currant tribe of leaves is to be preferred.

The cuticle or skin of plants is analogous, in its office, to the animal skin. Hairs, down, pores, &c., may be detected in the leaves of most plants, the pores being very numerous on them, and serving the double office of respiratory and perspiratory organs.

In some, or most grasses, in wheat, barley, and oats, a silicious skin is observed, which is composed of minute crystals of silica or flint. A coarse and rank grass, growing in stagnant ponds, affords it in considerable quantities.

Starch is a substance abounding in all plants, and presents a variety of appearances when the granules are obtained from vegetables. Fig. 55 illustrates the form of some varieties.

We need not remind our readers, that flowers are interesting objects for microscopic investigation, and their variety affords an almost endless field for research. The seeds and fruits of all kinds of plants are equally interesting; and perhaps the most instructive matter to which we can direct the attention of the student, is that of the process of germination, from the first change of the starch into sugar, until the radicle has made its appearance on the outside of the seed. We must not, however, enlarge here on this subject, because we shall have to enter fully into the consideration of these points in our section on Botany.

In the mineral kingdom, we find less variety of objects than in those on which we have been treating. This is partly owing to what we venture to term a comparative monotony of external form which exists therein, in contrast to the infinite variations of animated structures. The mineral, in fact, forms the raw material, which, in the hands of the Creator, has been fashioned into life. Organised existence, indeed, depends on the arrangement of but few elementary bodies. The means are surprisingly limited; whilst the number of products is only bounded by the skill of Him who in wisdom hath made them all.

There are, however, many points of interest to be discovered in the mineral kingdom, more especially in reference to the molecular and crystalline structure of bodies. It is true that we cannot perceive those ultimate atoms of which a mass is composed; but, as the power of our microscope is increased, so we can often detect the existence of definite forms utterly unperceivable by the naked eye. A most remarkable instance of this is found in the discovery of Professor Ehrenberg, who has detected the presence of exceedingly minute shells in common chalk; which indicates that that substance is simply the remains of an immense destruction of animalcules, whose exuviæ are now the only testimony of their previous existence. Similar facts have been brought to light during the examination of the bed of the Atlantic, preparatory to laying the electric cable between this country and America. Quantities of what appeared at first to have been sand, turned out to be the shells of marine insects, which had gradually accumulated in such quantities, as to present a bed thousands of miles in superficial area, and of considerable depth.

In geological researches, the microscope is of great value in determining the character of some strata, by the examination of the materials of which it is composed; and similarly, in the study of mineralogy, the amorphous or crystalline nature of masses can be detected. We shall, however, defer for the present any details on these subjects, reserving our remarks until we deal with them in their proper sections.

We have thus endeavoured to give some general idea of the diversified objects which fall under our notice, as subjects of microscopical examination in the three kingdoms—the animal, vegetable, and mineral; and conclude by saying, that our observations can only be regarded as indicating the nature, rather than the extent, of valuable knowledge which the microscope opens out to our understanding and examination.

TELESCOPES.

The next optical instrument to which we shall call attention is the telescope, with its various modifications of form, &c., which arise from the different purposes to which it is applied. Before entering on this subject, the student should have become familiar with the principles on which lenses and curved reflectors are constructed, and which we fully explained in the earlier pages of this work.*

Telescopes are of two kinds; namely, refracting and reflecting. In the former, the rays of light passing from the object are successively refracted by two or more lenses before reaching the eye. Of these, again, there are two classes, the ordinary and achromatic; in the latter, the coloured fringes produced by the employment of lenses of one kind of glass, as in common telescopes, are avoided by the use of lenses composed of two kinds; namely, crown and flint, which, by their different dispersive powers, destroy their natural tendency to produce coloured images. The principles on which achromatic lenses are constructed have been fully explained in our previous pages;† to which, for the sake of saving space, we must refer our readers.—Reflecting telescopes, on the other hand, receive the rays passing from a distant object on a peculiarly curved reflector, called a speculum; and these are reflected to the eye through an eye-piece. Hence, generally speaking, reflecting telescopes combine the principles of both reflection and refraction in their construction. Their forms have been varied according to the special views or requirements of their inventors. We shall select those most known and appreciated as the subject of our explanation; and give a general outline of the means employed to cast and to grind the speculum to a proper shape.

REFRACTING TELESCOPES.

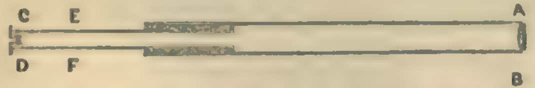
From the time of Galileo, to whom is generally accorded the merit of their discovery, telescopes of this kind have been the object of great care on the part of the instrument-makers. The value of a telescope depends, essentially, on its affording a well-defined, colourless, and correct image of the object viewed by it; and these results are only obtained by the employment of lenses as free as possible from either spherical or chromatic aberration.‡

For ordinary purposes a combination of lenses is required, which will present the image, to the eye of an observer, in a vertical position; or, in other words, the object must appear, in all respects, with the exception of size, as if it were viewed by the naked eye. In instruments used for astronomical purposes, this precaution or peculiar arrangement is unnecessary, because size and position are the chief objects which are sought after; hence, two lenses are sufficient in many cases.

Before proceeding to describe various forms of the refracting telescope, it may be as well that we should call the attention of the reader to the names of the two chief lenses—the *eye-piece* and the *object-glass*. The former term is applied to the lens which is placed *next to the eye* of the observer; whilst the *object-glass* is that lens furthest from the eye, and *next to the object;* it, indeed, first receives the rays of light entering the instrument. The definition of these terms will save us much circumlocution hereafter.

As nothing conduces more to interest the student in physical science than assisting him to the personal application of its laws and principles, we shall now give directions, by means of which any one may construct a simple telescope at a trifling expense, and yet of sufficient power to enable him to view many interesting astronomical appearances. We are indebted to Dr. Dick for the following description of an instrument of this kind, which we have slightly modified.

Fig. 56.



"Procure a double convex lens of about thirty-six inches focal length, and place it at the end of a tube, as at A B, Fig. 56. At thirty-seven inches distant from this lens fix another, as at C D, whose focal length is one inch. This should be fixed in a separate short tube, E F, which should be so made as to slide backwards and forwards in the large tube, for the purpose of adjusting the focus of the telescope to the eye. The following particulars require to be attended to. The aperture or opening which lets in the light at A B (that is, in front of the lens), should not exceed one inch in diameter, otherwise the image of the object will be somewhat confused. There should be a hole (or stop) in the focus of the eye-glass, C D, rather less in diameter than the breadth of the lens, for the purpose of excluding extraneous rays."

The tubes may be made of tin or zinc, and the insides should be blackened by painting them with a mixture of lamp-black and size. The stops at each end of the tube are easily made out of circular pieces of zinc, from the centre of each of which a neat round hole must be cut; that for the object-glass being an inch in diameter; and that for the eye-glass may be about half an inch. These can easily be soldered into their places on the tube. Such an instrument can be made for five shillings, and it will have a magnifying power of thirty-six times. Of the question of magnifying power, however, we shall speak more fully as we proceed. Simple as this form of telescope is, we may inform our readers that, in using it, they will be enabled to observe Saturn's ring, Jupiter's satellites and his belts, the lunar mountains, and the spots on the surface of the sun. For the latter purpose, however, the eye should be protected by means of a piece of dark-blue or blackened glass, placed between the eye and the eye-piece of the telescope, or the intensity of light and heat would be seriously injurious. We must also impress on all who may attempt to make such an instrument, the necessity of having the axes of the two lenses in exactly the same line. In other words, a line drawn through the centre of the object-glass A B, must, in a properly-constructed instrument, also pass through the centre of the eye-piece, C D. In the construction of optical instruments of all kinds, wherein two or more lenses are employed, this is certainly the "*pons asinorum;*" and neglect of this simple rule often involves a vast amount of annoyance and expense. Of this we met with an amusing instance in the case of a friend, who had expended upwards of thirty pounds in remedying a vast number of imaginary defects in an oxy-hydrogen microscope. On inspection, we found that the only fault existing was, that a brass arm, at each end of which a lens was fixed, required to be straightened, an operation which was performed in a few seconds by the aid of a vice.

We must now explain the cause and extent of the magnifying power of telescopes; and the simple one which we have just described will enable us to do so without danger of distracting the attention of the student by unnecessary detail, because the principles involved in its construction are equally so in every other form of telescope. In this telescope, the eye-piece is the medium by which the image produced by the object-glass is viewed and magnified; hence the magnifying power of any telescope of this kind will be in the ratio which exists between the focal distances of these two lenses. For instance, the focal length of the eye-piece, in the instrument we have described, is supposed to be one inch, whilst that of the object-glass is thirty-six inches; we thus obtain a magnifying power of thirty-six times. It also appears, that if the focal length of the object-glass is increased, and that of the eye-piece diminished, the magnifying power of the telescope is increased in the ratio which these two measurements bear to each other. We should here observe, that when we speak of the power of a telescope as magnifying so many times, it is meant that the diameter, or linear measurement, is increased. Of course, the total superficial result will equal the square of the linear one. Our telescope, for instance, is supposed to have a linear magnifying power of thirty-six times; but its superficial power will be equal to the square of 36, or 1,296 times.

In the following diagram, we have an illustration of the optical effects produced in the employment of telescopes (See Fig. 57). The larger lens at L being the object-glass, receives the rays of light, which, for our present purpose, we shall suppose to proceed from a star, A B; and are therefore, practically speaking, parallel to each other. The image of these rays is found at *a b*, and is, of course, inverted. The lens, or eye-piece, L′, magnifies the image, *a b*, in the manner represented at *b′ a′*.

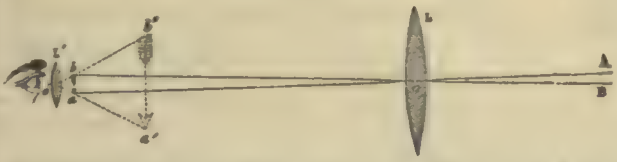
---

* See *ante*, p. 43, *et seq.*

† *Ante*, p. 53.

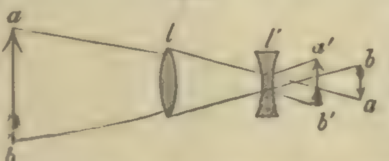
‡ *Ibid.*

Fig. 57.



In all telescopes, arrangements are made by means of which the relative distances between the object-glass and the eye-piece can be varied. This is for the purpose of adapting the instrument to the optical peculiarities of each observer; and is necessary, because the point of distinct vision varies considerably in different individuals, owing to the convexity of the eye in some, and its comparative concavity in others. We have already spoken fully of this subject in our remarks on the human eye;* to which we refer those of our readers who may be desirous of observing their application in reference to the use of telescopes, and other instruments generally. If two eye-pieces, of equal focal length, are placed successively between the object-glass and the eye-piece of the telescope represented in Fig. 57, the image will be presented to the eye in a non inverted form. This is, in fact, the arrangement employed in all ordinary telescopes used for viewing terrestrial objects; and the magnifying power of such instruments, as in the one we have been considering, is found by dividing the focal length of the object-glass by that of one of the eye glasses. The non inversion, however, of the image may be obtained by using a double concave eye-piece, instead of a convex one; the lens being placed nearer to the object-glass than at the point at which the rays passing therefrom would form an image. Fig. 58 represents an arrangement of this kind, in which *a b* is the distant object; *l*, the object-glass; *l′*, the concave lens; *b a*, the place at which the inverted image produced from the object-glass would be formed; and *a′ b′* is the non-inverted image, as observed by the eye of the spectator. The length of the instrument is much diminished by this arrangement; and hence it is a convenient form for opera-glasses, and other similar instruments, in which a moderate magnifying power, and limited field of view, only are required. In this instrument the two lenses are placed at a point equal to the *difference* of their focal lengths; whilst, when two convex glasses are employed, they are separated to a distance equal to the *sum* of their focal lengths. This instrument is generally called the Galilean telescope, from its having been employed by Galileo, the celebrated Italian philosopher.

Fig. 58.



Having thus described the ordinary forms of the telescope, we proceed to those of a higher class, in which chromatic aberration is almost wholly destroyed by the use of what are termed achromatic lenses. We have already explained the principles on which they are made, when treating on dispersion and achromatism;† it therefore only remains for us to describe the advantages derived from their adoption in telescopes. *Mathematically* speaking, two lenses may be so arranged in ordinary telescopes, that one, being the object-glass, shall have a focal distance of any assignable length, whilst the other, or eye-piece, may equally have one of the smallest extent; and the magnifying power of a telescope constructed of two such lenses, will, as we have already explained, be just in the ratio of the large focal distance of the object-glass divided by the short one of the eye-piece. But *practically*, there are limits, both of construction and use, which forbid the employment of lenses beyond a certain size and focal length. In the earlier days of telescopic discovery, object-glasses were used which had focal lengths varying from three to three hundred feet. Of these it will be unnecessary to do more than state, that their use was highly inconvenient. But to employ lenses of ordinary glass for high magnifying power, and at but a manageable distance from each other, was an unsolved problem until Mr. Dollond discovered, that a combination of lenses of two kinds of glass, whose dispersive and refractive powers would correct each other, effected that purpose. An object-glass composed of a concave lens of flint glass, into which is fixed a double convex lens of crown glass, meets the difficulty; and telescopes fitted with such, give not only a clear and distinct image, owing to an almost entire freedom from both chromatic and spherical aberration, but also supply another great boon to the astronomer, arising from this effect—namely, that of permitting the use of a telescope not exceeding a few feet in length, in place of those of the extraordinary size to which we have just alluded. In such arrangements, magnifying powers of astonishing extent may be employed; and thus the astronomer is supplied with an instrument whose capabilities are, practically, only limited by the means of its owner, and the skill of the workman employed in its construction.

REFLECTING TELESCOPES.

We now proceed to examine another kind of telescope, whose use is almost entirely confined to astronomical purposes, and in the construction of which great ingenuity has been manifested.

A reflecting telescope consists chiefly of three parts—namely, the *speculum*, or reflector, which receives the rays from the object (this takes the place of the object-glass in the refracting telescope); the *smaller reflector*, which is sometimes employed to receive the image from the large one; and the *eye-piece*, by means of which the image is viewed and magnified. These arrangements either vary or are modified in different telescopes, as we shall presently see.

It will be unnecessary that we should go over the same ground again in describing the general character, &c., of various forms of curved reflectors. This we have already done in a former part of this work, somewhat minutely; and we therefore refer our readers thereto,‡ and will proceed to describe each of the parts of the telescope in detail.

The speculum is generally made of an alloy composed of variable quantities of copper and tin; in addition to which, small proportions of other metals have been used. It is impossible to give the exact proportions in which these metals should be employed to obtain the best result. The object sought after is an alloy which shall be able to receive the highest polish; to retain this as long as possible; and yet, despite the hardness necessary to these ends, it must be sufficiently yielding to undergo the process of grinding. After being cast in a mould of suitable form, the alloy is annealed, and its brittle nature is thus tempered down. The process of grinding the casting into a proper shape then follows, and is effected by pressing on its surface a wooden mould which has been turned to a shape convex to the concave one which the speculum has to receive. Whilst the speculum is made to revolve, the mould, or grinder, is continually being covered with the powder employed in grinding. In some cases the speculum is stationary whilst the polishing mould or tool rotates against it. This operation is one of great delicacy, as on the perfection of shape and polish, the value of the speculum entirely depends. The largest speculum yet made is that belonging to Lord Ross. It has a diameter of six feet; weighs about three tons; and its focal length is about fifty-two feet. This reflector is composed of copper and tin united, in what, in chemical language, would be termed atomic proportions; or, in other words, such quantities of each metal were employed as are represented by those in which they would combine with acids, &c., in forming definite compounds.

---

* See ante, p. 43.

† Ante, p. 53.

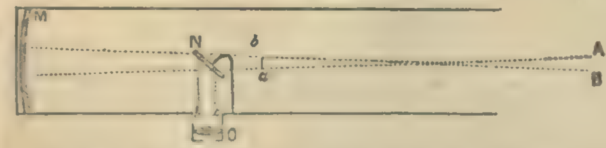
‡ See ante, p. 43.

Recurring to the proper shape of the speculum, we must refer to our remarks on spherical aberration,* and also to those on the properties of reflectors which have curves of one of the conic sections. In obedience to the laws of reflection from curved surfaces, the specula used in reflecting telescopes are usually made in the shape of a parabola; and thus, as far as possible, the evils of spherical aberration are avoided.

It will, perhaps, be more convenient that we should now illustrate the principal forms of reflecting telescopes which have been employed; and include, at the same time, the description of the small reflector and eyepieces specially adapted to their construction.

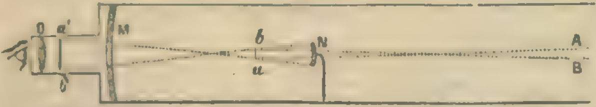
In the annexed figure we have a representation of Sir Isaac Newton's reflecting telescope. In this (see Fig. 59), M is the speculum on which the rays from a distant object, A B, impinge. These are reflected from M to N, which is a plane reflector, placed at an angle of 45° to the axis of the mirror. The image reflected from N is received and magnified by an eye-glass placed at O. The eye of the observer is of course placed at the opening beneath O, in a position which is extremely inconvenient. The mirror is placed between the focus *a b* and the speculum, and the image is formed at *a′ b′*.

Fig. 59.



The Gregorian telescope—so called after its inventor, Dr. Gregory—has a very different and much more convenient arrangement. In using an instrument of this kind, the observer views the image in a line which forms the axis, instead of being at right angles thereto, as in Sir Isaac Newton's telescope. A hole is bored in the large speculum, at its centre; and the rays of light reflected from the surface are received by a smaller concave mirror, which again reflects them to the eye-piece, and so they reach the eye of the spectator. Fig. 60 illustrates the construction of a Gregorian telescope; and the same letters are employed as in our last engraving, which will, therefore, at once point out the different parts, their position only being varied.

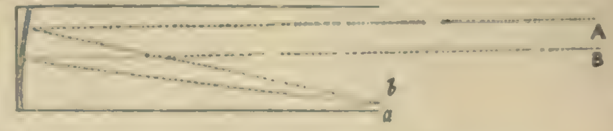
Fig. 60.



The Cassegranian telescope has a *convex* mirror, placed at N, instead of a concave one, as employed in the Gregorian. Both these forms of instrument have been variously modified, by astronomers and others, since the time of their invention.

The celebrated Sir William Herschel introduced another form of reflecting telescope, in which the observer looked down the tube enclosing the speculum, and of course with his back to the object. The speculum was placed at an angle with the axis of the instrument, and so cast the reflected rays towards one edge of the tube, at which they were viewed by means of an eye-piece. By this arrangement a second reflector, as employed in the previously described instruments, was rendered unnecessary. Fig. 61 represents a section of this form of telescope, in which the rays proceeding from A B are received by the angularly placed speculum, and reflected to *a b*, at which point they are viewed.

Fig. 61.



MISCELLANEOUS OPTICAL INSTRUMENTS.

HAVING mentioned the principal optical instruments, their construction and their uses, we now proceed to speak of those which, whilst highly interesting and useful, are still of comparatively minor importance, and, as such, will not require so extended notice.

Amongst these we may include the following: namely, Concave and Convex Mirrors, Spectacles, Magnifying Glasses, Burning Glasses, the Kaleidoscope, Debusscope, Thaumatrope, Kalotrope, &c.; of each of which we shall give a short explanation.

We have already explained the principles of concave and convex mirrors, and have, to some extent, alluded to their various uses. In doing so, however, we confined ourselves to strictly scientific illustration, and now propose to show a variety of amusing uses to which many of them can be applied. The same may be said of the other instruments to which we have alluded; all of which are constructed on the principles already laid down—modified, however, by peculiarity of construction and object.

As a variety of interesting experiments may be tried with both concave and convex mirrors, we may here enter more fully into the practical part of their construction, than we have in our previous pages.† We there stated, that unless a parabolic or elliptic form be employed, great loss of light and heat is sustained during reflection. For the purpose, however, of the following experiments, those of a spherical shape will answer very well. We may add, that such will be equally useful to the student during his studies of heat and sound; because they, like light, obey the laws of radiant forces.

Where the means of the student will permit, we advise the purchase of reflectors having a polished silver surface, which may be obtained of most of the optical instrument-makers. As, however, some of our readers may not be in a position so to do, and it being our desire to facilitate the repetition of all our experiments, the following directions may be useful; and if carefully carried out, they will enable almost any person to become practically acquainted with the laws and amusing applications of curved reflectors.

Either metal or glass may be used for the purpose. Generally speaking, metallic reflectors are preferred. A sheet of copper is to be hammered into a hollow shape, which can be readily done by any copper or tin smith. Instead of copper, tin or zinc may be used, as either of these metals will receive a good polish. They are, however, liable to tarnish; and just in proportion as that takes place, the value of the reflector for experimental purposes is diminished. The size of the reflectors may vary from eight to twelve inches in diameter, the reflecting power increasing in the ratio of the diameter. If copper reflectors be preferred, they should have their surface polished as brightly as possible, and be afterwards silvered by means of the electrotype process, or in the ordinary manner of plating. They then require repolishing; and such have the advantage of retaining the polish for a long time, and also reflect a larger amount of incident rays of light than any other metal.

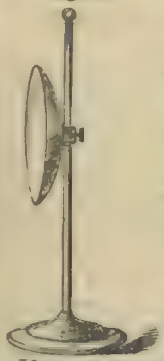
If glass be used, the *outside* surface may be "silvered" in a similar manner as is adopted for ordinary looking-glass if a *convex* mirror is required, and the *inside* for a *concave*: in either case, the side opposite to the reflecting surface is that which is to be coated with mercury. Reflectors of this kind must form a portion of a sphere; and a watch-glass, of the ordinary form, illustrates the shape of such a reflector. The "silvering" process is easily performed; and for this purpose the glass must be carefully cleaned, so as to be quite free from dust, spot, or dirt: a piece of clean tinfoil is to be pressed on one of its surfaces, so as to evenly cover every part; a little mercury is then poured on to the tinfoil, and evenly spread by means of a hare's foot, the hairs of which answer the purpose extremely well: a piece of thin tissue-paper may then be laid on the foil and mercury; and gentle pressure is to be applied, so as to force off the superfluous metal. The amalgam will adhere to the glass surface, and thus form a good reflecting coat. Either concave or convex reflectors are thus made; and although inferior to metals in their reflecting power, they will illustrate many interesting laws and applications of light. The most convenient way of arranging two reflectors is by placing them on stands, allowing them to slide on a rod, to which they can be fixed in any desired position by means of a binding-screw. Two should be obtained; and their appearance is illustrated in the annexed engraving. Referring to our remarks on curved reflection,[*] it will be found that we there enter fully into the explanation of such matters as focal distance, &c.; and these data, in reference to any mirror which the student may employ, must be ascertained by him experimentally, according to the rules we have laid down, and which we shall not repeat here. Such having been found, the following uses of curved reflectors may easily be examined, and several interesting experiments may be tried.

---

* See *ante*, p. 44.

† See *ante*, p. 43, *et seq.*

Fig. 62.



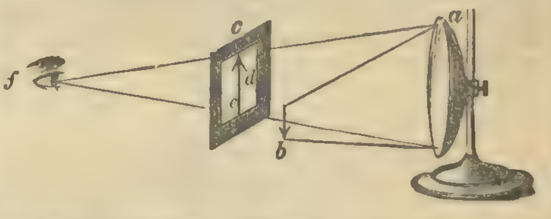
If a concave mirror be so placed as to receive the rays of light and heat from the sun, such will be condensed at the focal point, and powerful heat and light will be there produced. It does not matter whether the reflector is entirely spherical; for if made-up of a number of reflecting planes, the same effect is produced. Very powerful "burning-glasses" have been thus constructed, by building up a number of small plane reflectors in a concave curved form. By means of these the most refractory metal may be fused; and other substances which resist the heat of the most powerful furnaces are converted into the liquid state. Such reflectors have been in constant use in lighthouses, for the purpose of casting the rays of a lamp to a considerable distance. Perhaps the most remarkable instance of this sort was that of the reflection of the lime light in Scotland, during the survey made. On one occasion, the rays reflected by a concave mirror were distinctly perceived at a distance of ninety miles from their source. By similar means, the light produced by Holmes' magnetic arrangement was cast across the English Channel from the South Foreland lighthouse, and seen on the French coast, shining with great brilliancy. Concave reflectors, combined with lenses, are similarly employed on railways, as "signal lights;" and in any case, where a powerful and concentrated light is required, their use is of great value.

If an object be placed somewhat beyond the centre of curvature of a concave mirror, an inverted image of it may be seen in the air. This effect can be applied for a variety of amusing purposes. Thus, a jug of water, if its contents be poured out, will seem to be filling. An excellent plan of illustrating this amusing fact, is that of allowing thin smoke, as from smouldering brown paper, to pass between the observer and the mirror, when the inverted image will be distinctly perceived. The object is to be placed a little beyond the focus of the mirror in such experiments: the proper position is easily ascertained, however, by a trial or two. A person standing before a concave mirror, beyond the centre of curvature, will see an inverted and smaller image of himself; and by moving to and fro, the image will appear to advance till the centre of curvature is reached: passing that, the image will seem to recede from the observer.

Some amusing optical illusions may be effected by means of concave mirrors; one of which we shall here illustrate, and leave to the ingenuity of the reader to extend them in any other form he pleases.

If an object be placed, as we have just described, before a concave mirror, the spectator will see an inverted image, when placed in certain positions. If, however, the object be inverted, then an upright or vertical image will be produced. Availing ourselves of this fact, and placing before the mirror a screen having an opening of less diameter than the mirror, a spectator will see an image of any object placed between the screen and the reflector, apparently suspended in the air. Cameos, statuary, and other matters may be employed for the purpose; and for the amusement of young people, objects of a comic character may be employed. The arrangement will be fully understood by inspecting the annexed engraving; in which *a* represents the concave reflector; *b*, the object which must be inverted; *c*, the screen; *d*, the aperture therein; *e*, the image formed in the air; and *f*, the eye of the spectator. (See Fig. 63). The use of smoke, as before recommended, improves the effect; and if the desire be to startle or surprise, the mirror and object should be placed in one room, and the observer should look through an opening in a doorway, from the apartment in which he is placed, adjacent to that containing the mirror. The cause of the image will thus be entirely concealed from him; and the effect on his imagination will be proportionably increased.

Fig. 63.



From our observations on convex mirrors,[†] the reader will be prepared to find, that an image cast thereon will be magnified, at certain positions, instead of being diminished, as is the case when concave reflectors are similarly employed. On bringing an object near to a convex reflector, its image increases in size until the object and the reflector come in contact. This may be observed by watching the effect on the image of the face, whilst approaching or receding from a polished teapot, whose body, generally speaking, is of a convex form. Some concave and convex mirrors, which are sold by the opticians, have an amusing effect on the minds of persons looking thereon, especially if they are ignorant of the laws of optics. These mirrors are constructed so as to be viewed both widthways and lengthwise; and they respectively produce a ludicrously enlarged image of the face and features generally. These were often used as mirrors for the drawing-room, some years ago; and, perhaps, many of our readers may have seen them in houses furnished after the old fashion.

By means of concave mirrors of a cylindrical form, some very curious optical effects are produced, similar to those we have just named. Objects are painted, say of a landscape, &c., presenting an irregular or distorted form when seen by the eye. If, however, such are viewed by means of the mirrors we have been describing, they at once present a definite form. Such are called *anamorphoses*, on account of the peculiar change of effect which is produced by the arrangement.

SPECTACLES.

We have already mentioned, incidentally, instruments of this kind:[‡] we shall, however, enlarge on the subject, so that our readers may more fully understand the principles on which spectacles, &c., are constructed.

---

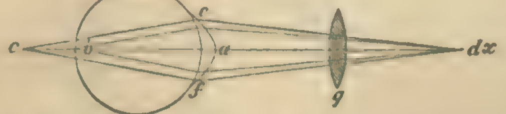
[*] See *ante*, p. 44, *et seq.*

[†] See *ante*, p. 45.

[‡] *Ante*, p. 49.

In our remarks on the structure of the eye,* we mentioned that the cornea is of a convex form, like an ordinary convex glass lens. It performs that office to the eye which a lens does to a microscope or telescope; that is, it collects the rays of light passing from any object. Each part of the eye, however, is exactly adapted to its special purpose, and any disarrangement, no matter how trifling, is followed by inconvenience. Even in early life, the eyes of some persons have the defect of being either too convex or too flat; and such defects are remedied by employing glasses or spectacles of an opposite character. Thus a highly convex cornea requires a concave lens; and one too flat is remedied by the employment of a convex glass. When the defect arises from the cornea not having sufficient convexity, then the rays of light received and refracted by it, have their focus behind the retina. The effect is very similar to that found when the lenses of the magic lantern, &c., are out of focus. The result, of course, is, that the person so affected suffers from great indistinctness of vision. This will be better understood by reference to the annexed diagram, in which it is supposed that the cornea has not sufficient convexity for the ordinary purposes of vision.

Fig. 64.

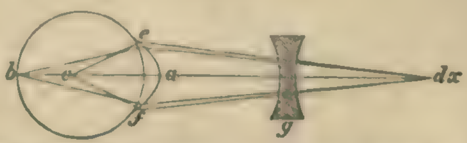


In Fig. 64, *a* represents the cornea, to which rays of light are supposed to be passing, unimpeded, from *dx*. Owing to the want of proper convexity, they pass on from *e f*, and do not reach the focus till they arrive at *c*, a point beyond the retina, *b*. If, however, a lens, *g*, be interposed between *a* and *dx*, then, by its convexity, it brings to a focus all the rays on the retina of the eye at *b*. The difficulty experienced by all persons so affected, is to find what is called their "sight;" that is, the focal distance of the lens, *g*. This can only be done by trial; and when successful, the result will be due to a choice of a glass whose focal point exactly falls on the retina when the spectacles are placed in their proper position before the eyes. The use of any pair of spectacles is, however, limited to special purposes; because, unlike the eye, they cannot accommodate themselves to the change of position or distance, in which objects are ordinarily found. A very ingenious arrangement, however, is sometimes employed. Instead of using one glass in each eye-hole of the spectacles, two, of different focal distances, are placed, so that four, instead of two lenses are employed. The two at the bottom of the spectacles are used for reading, sewing, and other purposes requiring close vision. The upper lenses are useful for viewing distant objects; and such a combination is of great value to elderly persons. We cannot help remarking on the imperfection of all human contrivances when put into comparison with those of the Creator. The eye, in its perfect state, can instantaneously adapt itself to any purpose for which we require it; all the intermediate steps of its arrangement are unperceived by us. But despite the skill of our best workmen, all attempts at imitating this are eminently faulty, partly from our ignorance of the necessary mechanical arrangement, and still more so from the absence of vitality in the instruments we employ.

We may now examine into the opposite defect of sight—namely, that in which the eye is too convex; and we need scarcely say, that the remedy is exactly the contrary to that we have just proposed. This will be at once understood by inspecting the following engraving.

In Fig. 65, we presume that the rays are proceeding from an object, *dx*, to the cornea, *a*. The cornea being too convex, converges the rays too rapidly, and they therefore come to a focus at *c*, between the cornea, *a*, and retina, *b*. If, however, a double concave lens, *g*, be interposed between *a* and *dx*, then the rays impinging on *e f* will not focalise except at *b* (which is the retina), providing the lens is chosen of the proper focal length.

Fig. 65.



In the absence of glasses, individuals affected in the manner to which we have been adverting, endeavour to accommodate either objects or the eyes, so as to partially overcome the inconvenience to which they are subject. Thus a short-sighted person, or one whose eye is too convex, sees better if the objects are placed close to the eye; whilst those whose cornea is too flat, remove the object to some distance from the eye. In either case, a temporary alteration of the visual focus is thus effected.

MAGNIFYING AND BURNING GLASSES.

We have classed under this head two instruments, whose properties arise from a similar cause—that of simultaneously concentrating the rays of light and heat when these two forces are present at the same moment. Of course our remarks are now chiefly directed to those circumstances in which solar or analogous influences are experimented on. In no case do we find the light of the sun unassociated with calorific effects; and as each force is subject to the same laws, these effects may be considered together.

In a former page,† we stated, that light, emanating from a distant source, does so in what may practically be considered as parallel rays. As such, the results are nearly coincident in a point called the focus. The effect varies according to the distance between the centre of the lens and the focus of the lens. If, however, the lens have a large curvature, and consequent distant focus, it will have the power of collecting from a greater area a larger amount of each radial force. We therefore find that the magnifying and burning power of any lens are not coincident. Added to this, we must take into account the effects of spherical aberration. The influences which may control the latter source of disturbance have been already discussed in our previous pages,‡ to which we must refer our readers.

Some extraordinary statements have been made in reference to the power of different kinds of reflectors and refractors, which have been employed for the purpose of concentrating the solar rays of light and heat. By large mirrors reflecting these forces, platina, quartz, and other refracting substances have been easily melted. The most successful experiments have been tried by means of reflectors which have been built up in segments, forming part of a sphere or ellipse. Such are most effective when arranged as reflectors of a parabolic form. Our own experience leads us to believe that there is a limit which entirely prevents the employment of solid glass lenses for such purposes. Experiments we have tried with a double convex glass, twenty-eight inches in diameter, and about six inches thick, showed a loss of light and heat, by absorption, &c., which rendered the lenses practically useless. In such instances, reflectors of the same size produced a far greater effect.

It has often been stated, that Archimedes, by means of burning-glasses, destroyed the fleet of his enemies. Whilst we congratulate him on his supposititious victory, we may prudently doubt its cause. Suffice it to say, that modern science, with all its assistants and adjuncts, has not, as yet, means at all equivalent to those which would be essential to the success of the hero we have named.

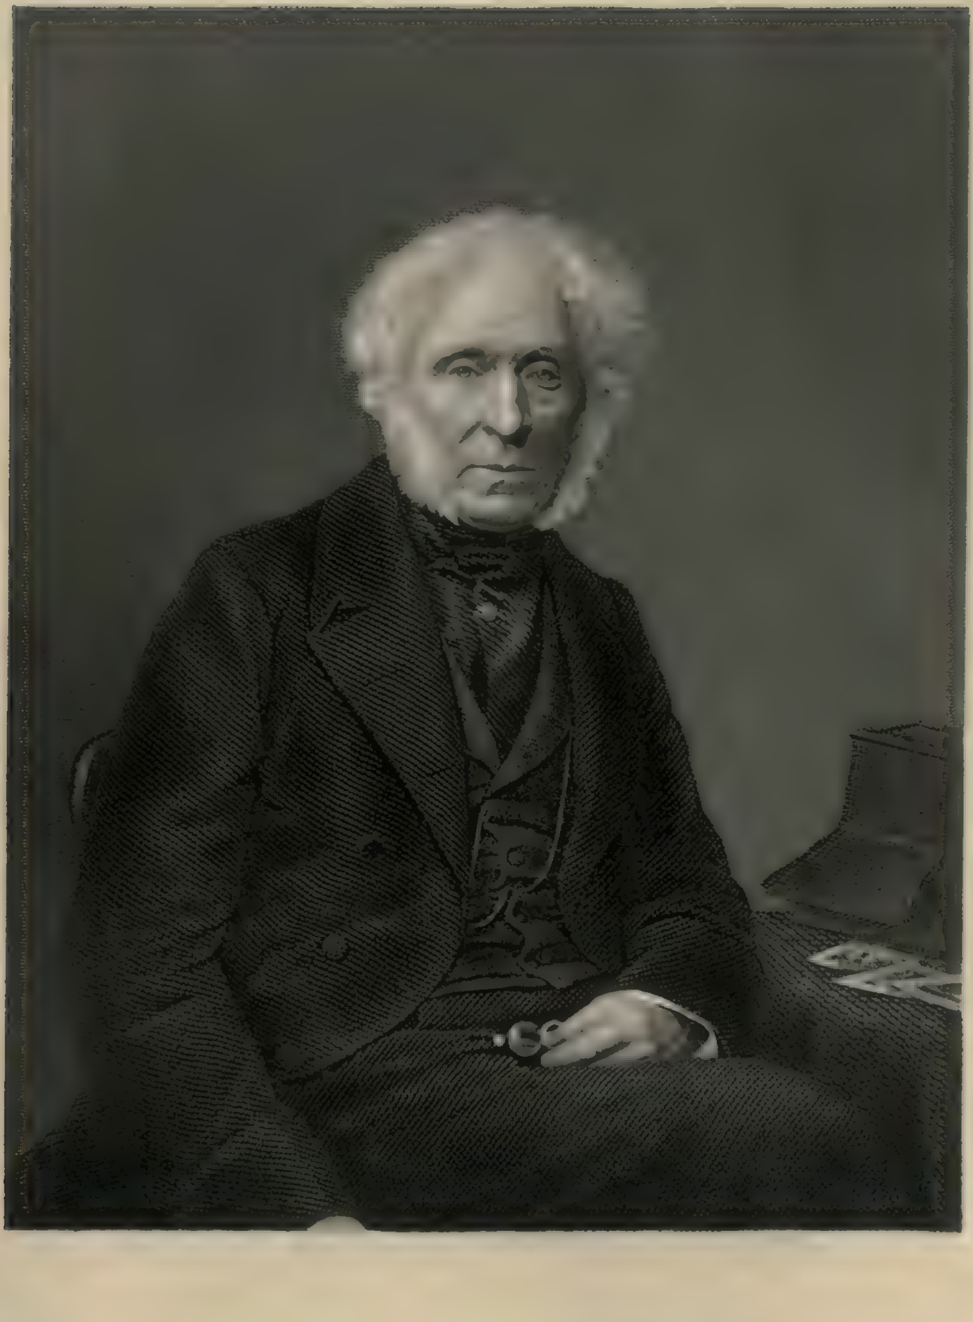
If convex glass lenses of large size are employed, it is advisable that they should be formed of blown glass—of

---

* See *ante*, p. 48.

† See *ante*, p. 44.

‡ *Ante*, p. 44.



[illegible]

[illegible]

course enclosing a cavity, which may be filled with a refracting liquid. This may vary from distilled water to strong hydrochloric acid, the latter having a strong refractive power, and also a peculiar action on the rays of heat and light. In naming this, we may presume that the majority of our readers will not have the opportunity of trying experiments on the large scale: we may, however, suggest the employment of two watch-glasses, or other glasses of large size, properly joined together, so as to hold a fluid. By such an arrangement a great variety of interesting results may be obtained; and, by a little patience, the student will greatly enlarge his knowledge of the effects of various liquids on the dispersion and refraction of the forces of light and heat. Any ordinary single or double convex lens answers the purpose of both a magnifying and burning-glass; one of the simplest of the kind being small blown-glass globes filled with water, which are often sold in the streets for employment of a microscope. It may not be out of place here to warn our readers of the risk run when water-bottles, or some kinds of window-glass, are in such a position that they can concentrate, lens fashion, the rays of heat and light. In the manufacture of crown glass, a thick piece is generally left in the centre of the plate, which, if suitably placed, will act as a lens. If either a water-bottle, or such a piece of glass, happen to be at their focal distance from any inflammable substance, it may just occur that they may bring the rays of the sun to a focus thereon. By such singular means toilette tables have been set on fire, and much destruction of property has ensued. Granaries and warehouses have, in a similar manner, suffered through this lens-like glass placed in the windows. These instances show how desirable it is that a general knowledge of scientific laws should be spread as widely as possible.

THE KALEIDOSCOPE.

The kaleidoscope, to which we shall first direct attention, was invented by Sir David Brewster; and has, for many years, been a source of pleasure and amusement, owing to the infinite variety and beauty of the forms it presents to the eye.

Externally it has the form of a cylinder; inside which are placed pieces of looking-glass, which act as reflectors. At one end of the instrument is an eye-piece, through which the observer looks; and at the other is a piece of ground glass, on the inner side of which rest the objects, which may be small pieces of coloured glass, or other coloured and transparent bodies. In whatever position the latter may be placed, they are continually and successively reflected by means of the mirrors; and hence any single object will undergo reflection, first from its own surface, and then from its image in one of the mirrors to that placed at an angle thereto. The result is, that, with several little objects, an immense variety of pleasing forms are produced; and the slightest change in their position instantly produces a change of form in the design. This, whilst being an essential character in the instrument, and productive of the most pleasing results, detracts from its value in an artistic point of view, as we shall explain when describing the Debusscope.

THE DEBUSSCOPE.

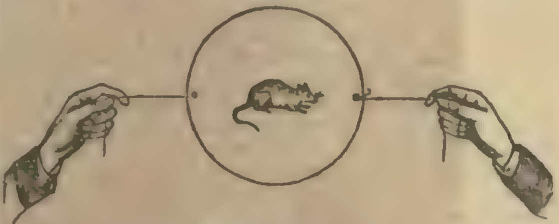
This ingenious contrivance is constructed on similar principles to those involved in the kaleidoscope. It, however, has the advantage of presenting permanently the patterns and forms it produces; and hence may become of great use to manufacturers and others who may avail themselves of it, in order to design patterns. It consists of two reflectors, set at an angle with each other; between which, the object whose appearance is to be multiplied is placed. Successive reflections produce, from the most heterogeneous object, the most pleasing and regular results. Thus, a piece of paper on which the most irregular scrawl may be drawn, will, owing to the composition of the rough design, produce a pattern of a most pleasing character. Even a piece of string, carelessly placed between the reflectors, may be made to assume any variety of form, and, simultaneously, to produce an equal variety of designs. Instead of having to look through the instrument, as in the kaleidoscope, the observer simply has to look on it between the two reflectors; and hence convenience and permanency are at once obtained. When the Debusscope becomes fully known, there is no doubt but that it will be highly valued. We are indebted to M. Debus for its invention; and hence its name.

THE THAUMATROPE, PHANTASMASCOPE, AND ROSE'S KALOTROPE.

In the earlier part of this section* we referred to the fact, that light travels with such speed as not to permit the eye to observe successive impulses on the retina, if such are more frequent than about eight in a second. Thus, the spokes of a wheel, if in rapid motion, present an indistinguishable appearance to the eye. If, however, a strong light is cast on them instantaneously, they will appear, for the moment, quite stationary; even the act of suddenly shutting and opening the eyes will sometimes afford the same result.

By means of mechanical arrangements this principle is capable of many interesting applications, in which what is termed the persistency of vision is employed, together with an intermission of light passing from the object to the eye. Generally speaking, the object is caused to revolve rapidly; and, by means of suitable contrivances, its surface is alternately, but rapidly, exposed or shut off; and so the effects of the thaumatrope, &c., are produced.

Fig. 66.



The thaumatrope, illustrated in the above cut, is made by painting, on the opposite sides of a round card, any two objects—say a mouse and a trap, or cage. Through the sides of the card a string is passed, each end of which is held by means of the finger and thumb. On twisting the card rapidly round, the mouse and cage come successively to view; but because the rays reflected from the two surfaces do not arrive at the same time on the retina, the effect produced leads a person to suppose that the mouse is running in and out of the cage. This arrangement often affords considerable amusement to young people; and, of course, the subjects may be varied to an almost unlimited extent.

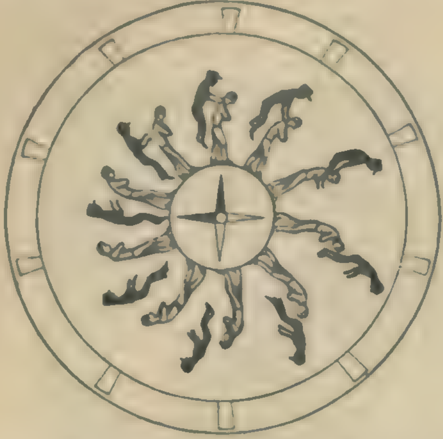
The phantasmascope acts on similar principles; but the arrangement is very different. A circular piece of cardboard, of any diameter, is fixed on a handle by means of a pin at its centre, on which it can freely turn round. On one side of the circle, figures, in different attitudes, are pasted or painted, and over each a small slit is made. On turning the card rapidly round, and looking through the slits on a looking-glass placed in front, the reflection of the figures, which seem to be in rapid motion and all alive, will be seen. Amongst many of the illustrations used are horses and men leaping gates, acrobats, &c.; all of which afford great amusement. The following engraving (Fig. 67) illustrates the construction of this singular toy.

Mr. Rose, of Glasgow, has invented a very interesting instrument, which he has called the kalotrope. It consists of a circular disc, on which are drawn, in deep lines, various curved figures. Before this is placed a kind of screen, perforated with divisions. Several of these are furnished, and thus the effect is varied. The disc is made to revolve rapidly by means of wheel-work; whilst the screen also revolves in front of the disc, either at a different speed or in a contrary direction. The result is, that the eye perceives the lines on the disc at variable intervals; and the intersection of the perforations on the screen, has the effect of producing to the eye the appearance of every form of geometrical curves, conic sections, &c. The results are exceedingly pleasing, especially when viewed by means of a powerful light. The arrangement is not susceptible of illustration by means of an engraving; and the instrument has not commanded that attention which its simplicity and beauty entitle it to.

---

* See *ante*, p. 42

Fig. 67



With this we must conclude our description of optical instruments, and pass on to another and important branch of the science of light, in which we shall have to deal with double refraction and polarisation. We have preferred to describe the application of light, so far as we have gone, in this portion of our work, because the instruments we have named are constructed and used in obedience to the principles and doctrines already defined, and have but a remote connection with the phenomena developed by double refraction. It may, perhaps, be as well if we give a kind of general *résumé* of some of the chief points of the affections of light to which we have hitherto directed the attention of our readers, so that, at all events, the student may retain a knowledge of the subject sufficient to guide him to those which we have yet to bring to his notice, each of which consists of special applications of previously enunciated truths, in an extended and practical form. It so happens that we shall have to introduce many matters, in connection with chemical science, with which some of our readers may be unacquainted. We shall, however, do so in an elementary manner, and, therefore, will not have to call for anything beyond the use of an ordinary intelligence in making our remarks understood.

At the commencement of this section, we first remarked on light as a latent force, and found that, although its chief source is the sun, still, by proper means, it could be educed from a latent state in bodies by certain processes; it is, therefore, in this, and in other respects, analogous to heat and electricity. We then proceeded to show that white light is compounded of coloured rays, which may easily be obtained by aid of the prism. We observed that each of these rays, or waves of light, varied from the rest, both with respect to the length of its undulations, their number within a given time, and their refrangibility.

Reflection, and its laws, were next reviewed; and the properties of plane, spherical, parabolic, and elliptical reflectors were investigated—this branch of the science being that of Catoptrics. We next observed, that a ray of light, passing into or out of media of different densities, undergoes refraction, or an alteration of its progress from a straight line, if the ray be incident on the refracting body at any angle from a perpendicular direction. As an expansion and application of this law, we next entered into an examination of various forms of lenses, and the direction which a ray of light takes through them. That perfection of lenticular arrangement, the human eye, next came under our notice, together with some peculiarities of vision to which some persons are subject.

The phenomena of colour, we stated, were produced by the absorption of all the rays of light except that which was reflected by the surface of the body to the eye; and we noticed that, whether such effects of colour were produced by reflection from a body, or by transmission through its substance, still the colour observed was due to the retention of every other ray except that perceived by us. The colours of thin plates of air assisted us to measure the length and frequency of the undulations of each ray presented by the prismatic spectrum. We then entered into the question of complementary colours, to which we shall have constantly to refer when dealing with polarisation.

Diffraction, dispersion, and achromatism then came under review, together with a peculiar form of dispersion, called epipolic.

Under the head of mono-chromatic light, we were enabled to discuss the effect of a single coloured light on surrounding objects, whereby we noticed that the colour of a body depended on that of the light incident on its surface.

An interesting discovery of Fraünhofer, that there are certain marks or bands in the spectrum, and an extension of these facts in the recent discoveries of Messrs. Bunsen and Kirchkoff, next engaged our attention. We shall add a supplemental chapter on this subject, as the best mode of giving a full account of the interesting facts which have been daily discovered, since those named in the remarks we made went to press.

We then described some of the effects of light on organised bodies; showing how animal and vegetable life are variously and powerfully influenced by that agent.

Having noticed some special ocular defects from which some persons suffer in respect to distinguishing colours, we subsequently explained, as an application of our previous remarks, the construction of the following optical instruments: namely, the camera obscura and lucida; the multiplying glass; the magic lantern, dissolving views, &c.; microscopes, and interesting objects to which they can be applied; telescopes, both refracting and reflecting; concave and convex mirrors; spectacles; magnifying and burning-glasses; the kaleidoscope; the Debusscope; the thaumatrope; the phantasmascope; and Rose's kalotrope.

We may here make a few remarks on the peculiar phenomena which we shall more particularly deal with in our section on chemistry: we refer to phosphorescence and fluorescence. Phosphorus and fluor-spar, with many other bodies, have the power of spontaneously emitting light; and in the case of phosphorus, this is owing to a slow combustion, or its union with the oxygen contained in the atmosphere. This effect, however, may be observed in many animal substances; hence the luminous appearance of crabs, &c., and the phosphorescence of the sea, which proceeds from extremely minute creatures swimming on its surface.

Fluorescence has obtained its name from the spar we have named; and is developed by heating that substance. The two terms are frequently applied to appearances similar to those we have referred to, but arising from different causes; hence we speak of the phosphorescence of the electric discharge. We can fully understand that the student may find some difficulty, whilst considering the phenomena of which we are taking notice, in reconciling the fact of the spontaneous production of light, with the remarks we have previously made on the doctrine of latent forces. Indeed, it would seem, at first sight, that light, in such cases, produced itself; but we must bear in mind, that chemical action is really a form of motion, that arises from the attraction which one element may have for another; and just as the sun and the earth have a mutual attraction of gravitation, and so tend to approximate—the chemical attraction subsisting in bodies, tends also to bring them into intimate union; and, as such, is the promoting cause of phosphorescent effects. Heat, of course, produces the appearance of fluorescence; and, in that case, we therefore have one force producing another; and a sufficient cause is therefore existing towards the production of its consequent effect.

We shall now pass on to the subjects of Double Refraction and Polarisation, in which the reader will find that all his previously acquired knowledge will be called into requisition. These will be succeeded by articles on Artificial Illumination and Photography—two subjects of the deepest interest as applications of the force or agency of light.

CHAPTER II.

DOUBLE REFRACTION AND POLARISATION OF LIGHT.

We have now to enter on a most interesting branch of scientific inquiry, which, although of comparatively recent origin, has attracted the profound attention of the most eminent living philosophers.

The reader will have already become acquainted with many of the changes which a ray of light is subject to when it is either reflected from, transmitted through, or refracted by various substances; and it will be essential to our progress that he should bear in mind the various laws on which we have already dilated. This will be more fully seen when we have to deal with phenomena which depend both on reflection and refraction, yet in other conditions than those which we have previously inquired into.

In a former part of this section, we fully entered into the consideration of the single refraction of light. We then observed, that when a ray of light passes from a rare through a dense medium, and *vice versâ*, it does so in a line varying from that in which it had previously travelled; in other words, it suffers refraction: still, however, no visible change in its nature is apparent; its direction alone being affected. There are, however, a great variety of substances which have the power of not only refracting light singly, but also of dividing a ray into two parts—an effect called *double refraction*. The best known instance of this kind of bodies is the common Iceland spar. If a piece of it be placed on a line drawn on paper, or on a wafer, &c., a double image of the object will be perceived. The rays proceeding from the object are divided into two pencils by the peculiar structure of this doubly refracting body; and hence the effect on the eye is to cause the perception of a double image. To make this more easily understood, we annex an engraving illustrating the case of double refraction by a rhomb of Iceland spar, together with one showing the direction of the rays of light passing through a rhomb of that substance.

Fig. 68.

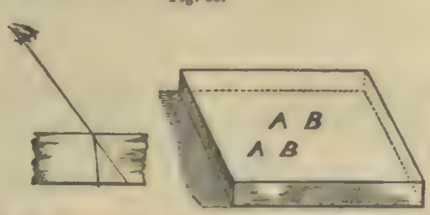


Fig. 68 represents a piece of Iceland spar, placed on a paper on which the letters A B are printed. These, when viewed through the spar, appear double, as illustrated in our diagram. Fig. 69 shows the division of the ray of light into two pencils, *e o*, when passing through a doubly refracting substance. The effect of double refraction must be owing to some peculiar arrangement of the particles of the refracting body; or, in other words, to its molecular structure.

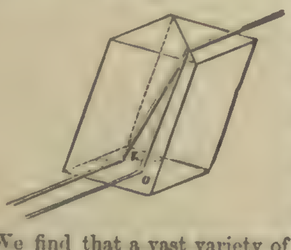
Fig. 69.

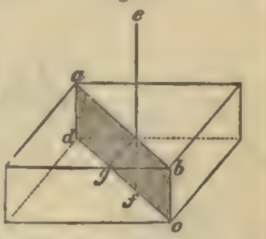


We find that a vast variety of bodies, which, in their ordinary state, do not possess this property, may be made doubly refracting by means of pressure, by changes of their form by mechanical force, by suddenly heating and cooling them, and through any cause which alters the relative arrangement of their particles. Glass may be taken as an illustration of this class of substances; for although but single refracting in its ordinary state, it affords the phenomena of double refraction on being suddenly heated or cooled, or when under pressure or distortion.

We have already stated that the phenomena of double refraction is caused by a ray of light, on entering certain bodies, being split into two rays or pencils, which are separated thereby at an angle from each other. In bodies of a crystalline character, there are what are called optic *axes*, or fixed lines; and on the position and nature of these, the direction, and consequent refraction, of the ray of light depends. Some bodies have but one, and others two axes of double refraction. As an instance of a substance possessing one axis, we may name Iceland spar; and one possessing two axes we find in crystallised nitre. These two classes of bodies are respectively termed uniaxial and biaxial crystals.

We must now explain more clearly what we mean by an optic axis; and for this purpose we refer to the annexed engraving, which represents a rhomb of Iceland spar.

Fig 70.



In Fig. 70, we have a representation of a piece of Iceland spar. If a line is supposed to be drawn from *a b* to *b c*, this would represent the axis of the mass. Let *e* be a ray of light falling perpendicularly on the surface of the rhomb. Now if this were of glass, the ray would, according to the laws of single refraction, pass through unchanged, because perpendicularly incident thereon.* But when falling on a rhomb of Iceland spar, the ray is divided into two parts, of which *e f* is the ordinary ray, and *e g* the extraordinary ray. If the ray of incident light fall obliquely, still the ordinary ray is obedient to the laws of single refraction, whilst the extraordinary pursues a course divergent from the optic axis of the crystal, and at various angles of position thereto, according to the substance under examination. In observing the two images presented by a piece of Iceland spar whilst it is turned round over a spot, it will be found that the extraordinary ray moves in a circle, whilst the ordinary remains stationary. The relation of these two rays in reference to the optic axis of the crystal, may thus be examined by the student, and a knowledge of their mutual divergence and position in various circumstances is at once obtained. The optic axes are respectively positive and negative when the extraordinary ray is bent either to or from the geometrical axis of the crystal. As an instance of some bodies possessing positive axes, we may mention quartz, ice, &c.; whilst Iceland spar, the tourmaline, prussiate of potass, &c., have negative axes. We shall be able to see the application of this law more fully when we enter on the consideration of polarised light, and its resulting phenomena of the production of colours, &c., under certain circumstances.

We must here state, that the velocities of the ordinary and extraordinary rays in a refracting medium of the kind we are now dealing with, differ from each other; that of the extraordinary ray varying according to the angle it makes with the axis of the crystal, whilst that of the ordinary is constant. The larger the angle which the extraordinary ray makes with the axis of the crystal. the greater is its velocity; and its relation to that of the ordinary ray is dependent on the positive or negative character of the crystal.

---

* See *ante*, p. 45.

POLARISATION OF LIGHT.

PERHAPS there are no phenomena of which it is more difficult to convey a popular description, than those connected with the polarisation of light. We shall, however, endeavour to meet the difficulty by affording simple means whereby a ray of light may be polarised; give directions for constructing apparatus called polariscopes; and after thus conveying a general idea of the effects of polarisation, which the student may easily become acquainted with, we shall go more deeply into the facts and principles of this interesting branch of physical science.

The student will naturally ask, "What do you mean by polarised light?" And we will endeavour to answer the question, by pointing out certain effects which occur when a ray of common light is reflected or refracted at certain angles.

When speaking of the reflection of light,* we stated, that a ray, incident on any reflecting surface, was reflected at an angle equal to that of incidence. If, however, a ray of light fall on a plate of glass (which should be blackened on the back), placed in such a position that the ray is incident at an angle of about 57°, then the ray is divided into two parts, one of which is reflected, and the other is absorbed. If the reflected ray be received by another glass plate, placed so that the ray reflected from the first is received at an angle of 57° on the second plate, the ray will be polarised; and it has thus acquired certain properties greatly differing from those of ordinary white light. The student will understand this better by constructing the simple apparatus represented in the annexed engraving, which will afford him an elementary polariscope, or instrument by which rays of polarised light may be obtained.

Fig. 71.

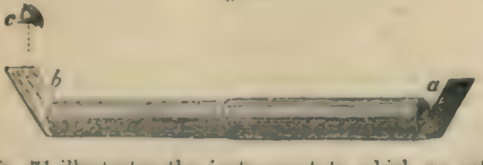


Fig. 71 illustrates the instrument to which we refer. To construct it obtain two tin tubes, each six inches long, and about two inches in diameter; and one of these should be so much narrower than the other that it may slide easily and yet firmly therein. The insides of the tubes should be blackened by coating them with a mixture of lampblack and size. This will prevent any reflection of light internally, which would interfere with the desired result. At one end of each tube a piece of plate glass, blackened also at the back, must be placed; and each of these is fixed at an angle of 33°, so that a ray of incident light may fall, at an angle of 57°, on the surface of either.

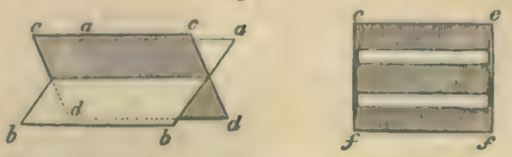
If the eye of the spectator be placed as at *c* in the engraving, he will perceive the reflection of the ray from *a*; but if the glass, *a*, be turned round to the extent of a quarter of a circle—that is, 90°—he will find that the reflection of light from it is almost entirely lost. On turning *a* round to one-half of the circle, or 180°, so that *a* and *b* shall be in entirely opposite positions, it will be observed that the light reflected from *a* will again appear. If the glass be further moved so as to have passed through three-quarters of the circle, the light will be again cut off. On continuing the motion of *a* until restored to its primary condition, the reflected ray will again appear; and thus we observe, at each quarter of the circle, a reflection or loss of the ray incident on *a*, as viewed from the reflected surface, *b*. Now this only happens when each of these glasses is placed at a certain angle, as already remarked; and such is therefore called the *polarising angle* of the substance employed for that purpose. It is at this angle that the greatest polarising effect takes place, although such also occurs at other angles, but, of course, to a diminished extent.

Another mode of producing similar effects, is that of using two plates of a mineral called tourmaline, which may be obtained of the optical instrument-makers. Ordinary light—as of the sun, a candle, or a gas flame—is easily seen through one of these plates, or through two if placed over each other in certain positions. If, however, one plate be held before any source of common light, and the other be gradually revolved through a complete circle in front of it, and next to the eye of the observer, it will be noticed, that at every quarter of a circle, or 90°, the light will be alternately exhibited or extinguished, just as we stated would be found in using the simple apparatus already described. There is, however, this difference between the two processes—the first produces the result of polarisation by *reflection*, and the latter by the *transmission* of the rays through a refracting substance. The student will thus see, that what is called polarisation, is equally effected on ordinary light by reflection and refraction.

Having thus shown how light may be polarised, we proceed to describe the nature of the effect produced; and this, perhaps, can be best done by pointing out the difference which exists between a polarised and a non-polarised ray. An *ordinary* ray will be equally transmitted and reflected through or from the body on which it may fall; whilst a *polarised* ray is not thus indifferent to the physical nature of such body; and, moreover, will only pass in such directions through it, or be reflected from its surface, at certain angles varying for each material employed. Hence, in polarisation, a ray of ordinary light acquires such properties as connect it essential with the physical nature of the substances on which it may fall, or pass through; and this is evidenced from the fact, that it will not pass through some substances at certain angles; that it will similarly not be reflected at some angles of incidence; and lastly, its relationship to doubly refractive structures is eminently different to that it maintained previous to polarisation. On the latter property we shall have to enlarge more fully hereafter.

A variety of illustrations have been offered, in scientific works, for the purpose of familiarising the eye and the mind of the student with these facts. One of the simplest of these is represented in the annexed illustration. (See Fig. 72).

Fig. 72.



In Fig. 72, let *a b* represent a piece of cardboard, fixed so as to form a cross, with another piece, *c d*; and let *e f* represent a flat piece of card, through which parallel openings have been made from one side to the other. Now, supposing either end of *a b c d* be presented to *e f*, only that portion parallel to the openings of *e f* could be introduced; the other part of the cross, being at right angles to these openings, could not of course pass through. Now, in a similar manner does the plate of tourmaline act on the ray of light; and in the above we have illustrated the effect observed by turning round the tourmaline plates—namely, that of the rays being alternately transmitted or extinguished. Our remarks and illustrations are, for the present, entirely confined to the consideration of what is called *plane polarised light*; or, in other words, we refer to the absorption or transmission of light, solely in connection with imaginary rectilinear planes, in or about the bodies employed for our purpose.

---

* See *ante*, p. 41.

There are no natural analogies which we can offer as illustrative of such phenomena. It is true that we have magnetic polarity, or that power by which a magnetised needle arranges itself in reference to the magnetic poles of the earth. But such considerations fail to assist us; and it will perhaps be better, after the introduction which we have here given, to describe various polariscopes, by means of which we may be able to investigate the subject experimentally, before proceeding to consider the more intricate parts of our subject.

TO CONSTRUCT POLARISCOPES.

It is generally supposed that expensive apparatus is required for the purpose of studying the phenomena of polarisation. This, like many other ideas of matters required in the pursuit of science, is entirely erroneous. It is true that extreme accuracy, such as is required in exact research, can never be obtained except by employing instruments of the most careful construction. We have been at some pains to find the cheapest and readiest form of polariscope, of which any of our readers can avail themselves; and after trying several experiments with this view, we can recommend the following, which will, at least, serve as an introductory arrangement to the beauties of this branch of experimental science. In every polariscope there are two essential parts; namely, the *polariser* and the *analyser;* the former receives and polarises the incident rays of light, and the latter presents to the eye the polarised ray either by reflection or by refraction.

A polarising plate is easily made by coating a sheet of level window-glass, on one side, by means of lampblack and size, or by holding it over the flame of a candle or gas-light till completely blackened. We have found that the flame of a "composite" candle answers best for this purpose. The glass should be about eight inches square, and should be placed on another piece of blackened glass; the two being separated by means of thin slips of card at their edges, and the black surfaces should face each other inside. This will prevent the black from being rubbed from their surfaces whilst experimenting with it. We may here remark, that so easy is it to obtain a polarising plate, that we have often employed the slates of a roof when wet by rain, or the horsehair covering of a parlour chair, for the purpose; although the latter would scarcely claim the dignity of a scientific instrument. To prevent the glasses from slipping when in use, their edges should be pasted together by means of narrow slips of black paper.

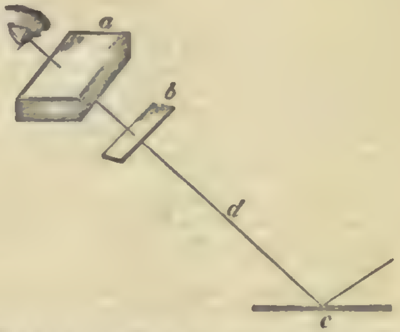
The analysing plate is made by piling up twelve pieces of perfectly clean thin window or microscopic glass, which must be closely packed together. They may be three inches long, by about two inches wide; and their edges should be pasted by means of paper, &c., so that they may form a compact and immovable mass, as represented in the next figure. This also excludes dust and dirt.

Fig. 73.

To use these arrangements for the purpose of polarising light, place the blackened glass plate at a window, so that they may reflect the image of a white cloud; or place before the plate a sheet of ground glass, so that the light falling on the polariser may have a uniform white tint. The analyser should then be held in the right hand, and the eye should view the plate through it at a distance of about four feet. On looking through the analyser in one direction, the blackened plate will appear much of the same colour as if viewed by the naked eye; but if the analyser be turned round through a quarter of a circle (90°), and the blackened plate be still observed, it will be found, that nearly all the light from its surface is lost. Thus, one of the phenomena of polarised light may be noticed. If the analyser be turned round through half a circle, the light will again appear; if through three-quarters, or 270°, it again vanishes, until the analyser has regained its original position between the eye and the observer, when the light reflected and polarised by the black plate will again be observed in its original intensity. If a piece of mica be now interposed at a distance of a few inches from the analyser, and between it and the polarising plate, it will present, if placed at the proper angle, a beautiful appearance. The most magnificent colours will be seen; and if the analysing plate be steadily turned round, to the extent of 90°, whilst the mica is held in the same position, the original colours will entirely disappear, and their complementary colours succeed them.* Instead of a piece of mica, a thin plate of the yellow prussiate of potass may be used; and the effect is, if possible, still more brilliant.

To enable the student to employ this simple piece of apparatus successfully, we append an engraving, showing as near as possible the relative position of the different parts. We are aware that a little difficulty may be experienced, at first, in placing each at its proper angle; but after acquiring this, the student will find the arrangement extremely convenient for many purposes.

Fig. 74.



In Fig. 74, *a* represents the bundle of glass plates forming the analyser; *b*, the plate of mica under examination; *c*, the polarising plate. The direction of the polarised ray is from *c*, through *d*, the mica plate, the analyser, and thus at last it reaches the eye. In looking through the analyser, the long edge of the glass plates should be held as to make such an angle with the nose as that the observer may see the line of light in a plane passing about an inch from the lower end of the top surface of the analysing glass; and which, if carried through the bundle of plates, would almost touch the extremity of the under surface of the bundle, which will thus be at an angle of about 57° with the horizon. A most beautiful play of colours may be produced by gently moving the plate of mica about in various directions. This, however, the student will soon discover. By splitting pieces of mica up into plates of different thickness, each piece may be made of such a size as to reflect one colour only, and its complementary. A sheet of mica, therefore, presents a great number of beautiful appearances, owing to the various thicknesses of which it is composed. One of the readiest ways of splitting that substance is by making it red-hot; a great number of parallel plates are thus formed.

Having described this apparatus, which may be made for a few pence, and which will enable any one to become acquainted with some of the magnificent effects of polarised light—we proceed to point out other arrangements answering the same purpose, but which are more complete in their construction.

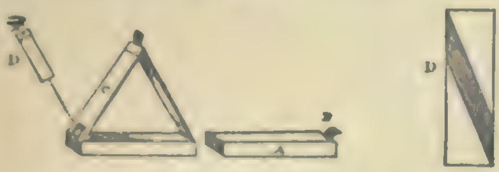
The most simple of the kind that we have yet seen is that constructed by Mr. Bestall, of Kennington; one of which is exhibited at the South Kensington Museum. The following engraving illustrates its arrangement; and the description we give is in the inventor's own words.

Description of Bestall's Polarising Apparatus.—This apparatus for showing the beautiful phenomena of polarised light in glass, acids, salts, crystals, &c.—adapted for night or day—consists of a polarising mirror, a glass stand to give the proper angle, and an analysing tube; all of the most simple and cheap form, with all the properties of the most expensive apparatus.

---

* See *ante*, p. 52.

Fig. 75.



Directions for using Bestall's Polarising Apparatus.—Hold the red box, A, Fig. 75, in one hand; pull the red tongue, B, with the other—that will place the mirror and the glass at the proper angle. Place the black mirror in the box, A, with the reflecting part upwards; and the glass for giving the angle on the mirror, as in the drawing. Place the object on glass, C, and fix the ground glass to the light. Place the apparatus on a table by the window, for day; for night, a light to reflect about half-way up the ground glass should be used. Hold the analysing box, D, to the eye, turn it gently round, and sit about two or three feet from the apparatus; look at the object, and so obtain the phenomena of polarised light.

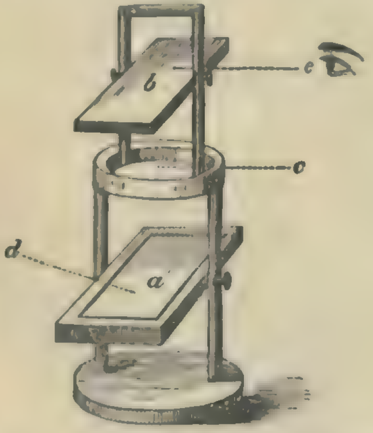
By turning the analysing tube round, the primary and complementary colours will be afforded.

The analysing plates can be taken out of the tube to clean them; but be particular in replacing them in their former position.

Having tried the above-described arrangement, we can unhesitatingly state that it is a most useful instrument. It has, also, the recommendation of being as cheap as it is effective.

The most commonly used form of polariscope is that represented in the annexed figure. In this apparatus, polarisation takes place by reflection, and the analyser is also a reflector. It is an extremely convenient arrangement for the purpose of showing, at alternate angles of 90°, the phenomena of complementary colours. We observe, that at the lower part of this polariscope (Fig. 76), a square frame, containing a few glass plates (the last of which has been well blackened), is fixed. On this the ray of common light is allowed to fall at an angle of 33°. Being reflected from the surface, the polarised ray reaches the analyser, which consists, also, of a number of glass plates (the bottom one being blackened). The object to be viewed is placed on an intermediate stage, and the eye of the observer sees the effects of polarised light by means of the top mirror.

Fig. 76.



In Fig. 76, *a* represents the polarising plate; *b* is the analysing plate; *c* is the stage on which the object to be examined by polarised light is placed. The frame holding the analysing plate, *b*, is movable, so that it may be turned round, and be so arranged at any angle with the polarising plate. The angles are measured by a graduated rim, as observed in the engraving; *d* shows the direction of a ray of light incident on the polarising plate, *a*, which, passing to *b*, is reflected to *e*. This is the position in which the eye of the observer is placed. Both the analysing and polarising plates are placed on pivots similar to those employed in common looking-glasses. This arrangement permits of their being placed at any angle. In employing this instrument, the polarising plate should receive a ray of light at an angle of about 57°; and the analysing plate should be similarly arranged, and receive the ray from *a*, at an angle also of 57°. A considerable beam of polarised light may be thus obtained. We may remark, that such an apparatus may easily be constructed by any cabinet or looking glass manufacturer, by following the detailed instructions we have here given.

The arrangement of the polariser and analyser, in our engraving, throws the two at such an angle as will afford the ordinary phenomena of polarised light. By turning the analyser to an angle of 90° with the polariser, the complementary colours to those seen in any object by the represented arrangement will be observed most readily. We may remark, that 0°, 180°, and 360°, are the relative positions of the two plates for the *reflection* of the polarised ray, and 90° and 270° for that of its *absorption* or *extinction*. At these the complementary colours become visible. We have hitherto confined ourselves to the description of the simplest forms of polariscopes. Others of a more exact character, in which tourmaline plates, Nicol's prism, &c., are employed, will be described as we proceed.

GENERAL PHENOMENA OF POLARISED LIGHT.

From what we have stated in reference to the construction of polariscopes, our readers will have perceived, that all the effects of polarised light depend on the peculiar molecular construction of bodies. Indeed, one of the most valuable uses, in a philosophic point of view, to which the polariscope can be applied, is that of detecting differences which exist in the arrangement of the atoms* of which a mass is composed. We are enabled to determine, with a most astonishing precision, the characteristics of two or more bodies having exactly the same chemical constitution, and yet differing in their purely physical character. An interesting illustration of this fact is found in the case of sugar, and many kinds of starch, which, whilst presenting the same results as to quantity and proportion when subjected to the test of chemical analysis, exhibit astonishing differences when examined by means of the polariscope.

To those who take a pleasure in studying natural laws, and their special application, this fact must necessarily be one of the most interesting kind. A number of bodies is taken, each member of which has the same elements for its constitution; and each of these may be found exactly in the same ratio in one as in the other; yet the whole group differs individually. Nothing can seem more heterogeneous than sugar and starch; and yet, chemically, their constitution is the same. Then, again, we have the diversity of character in the same family of starches, as potato, rice, arrowroot, tapioca, flour, &c.; each of which differs from its fellow in many of its qualities; such difference, however, almost entirely escaping the keen eye of the practical chemist. Again, some bodies have so singular a relation to, or power over, a ray of light passing through them, as not only to alter its course, as in the ordinary case of single and double refraction, but also to divide or split it, and so to produce a series of phenomena of the most extraordinary kind. Hence we perceive the effects of plane and circular polarisation.

We may here remark on the fact, that whilst the generally received idea invests the qualities of the taste, smell, &c., of bodies with a chemical character, the laws of polarisation tend to enlarge our views in reference to such qualities of bodies, and to give us an insight into other causes than those which we assign to many effects observed in daily life. We should, perhaps, trench too greatly on the doctrines of chemical science, were we to fully express our views on this subject, and illustrate them by the countless instances which we could adduce, wherein a change in the molecular constitution of a body modifies its character. We may, however, take the case of alcohol, and its products. Retaining the same elements—alcohol, ether, acetic acid, oxalic acid, &c., are all producible from one substance; namely, common sugar. By means of what has been termed catalysis, alcohol is easily converted into acetic acid; and yet the only agent required is one—platina, which does not undergo the least perceptible change during the process: similarly, the same metal can effect the union of oxygen and hydrogen, especially when presented to a mixture of those gases when it is in a state of minute division. Instances of the rearrangement of atoms (purely physical in its character) may be adduced, wherein no chemical change is perceived, no external alteration made manifest; and yet no sooner do we employ a ray of polarised light, than we are enabled to detect differences and effects which otherwise would entirely escape our senses. Annealed and unannealed glass, Iceland spar, and Arragonite, the different kinds of oils, &c., are illustrations of such occurrences. We must, however, not stop at a general view of the matter: our desire has been to give the student a distant but comprehensive view of the almost unlimited nature of our subject; and having attempted this, we shall endeavour to lead him, step by step, among the arcana of this interesting branch of physical research.

---

* See Introduction, p. 1.

We shall presume that the student has provided himself with some form of polariscope such as we have already described; or, in the absence of this, the following will be necessary; namely, two bundles of glass plates, each perfectly clean, and to the number of ten in each bundle. These should be fastened together, as illustrated previously.* A large piece of plate or window-glass, which has been blackened on one side, either by lampblack or the black varnish used by photographers, and a few pieces of mica, on which to try various experiments, will be required. The latter may be obtained in most of our large towns, as it is largely employed for the purpose of making lamp-protectors, and for other purposes.

Furnished with these, our readers may readily study all the leading phenomena of polarised light. Indeed, the whole of the results we shall for the present refer to, may be produced by the simple arrangement we have named. This is another illustration of the fact, that science, even in its most refined branches, may be experimentally studied at a trifling cost.

Having placed the polarising black plate with the polished surface upwards, so as to receive light thereon from a white cloud, or from a lamp screened by means of a piece of ground glass, its surface may be viewed through the bundle of glass plates, or by means of another piece of blackened glass placed above it. If the latter be employed, the polariser and it must be at similar angles (about 57°) with the horizon. The angle at which the bundle of glass plates is to be held, depends on their number. Their position, however, has already been illustrated.† The observer will find, that if either the bundle of glass plates or blackened analyser be held in the proper position, then the light passing from the polariser will alternately be visible or be shut off, as the analyser is turned through each quarter of a circle; so that through 360°, there will be, alternately, a phase of light, and one in which the light entirely disappears.

As we have already remarked, this is due to the peculiar change which light undergoes when it suffers repeated reflection, refraction, or double refraction. The result is obtained by reflection simply when the polariser and analyser are two pieces of blackened plate, such as we have described. The result occurs, partly by reflection and by single refraction, when the polariser is a blackened glass plate, and the analyser a bundle of plates. The same result is arrived at by single refraction solely when two bundles of glass plates are used, placed at the proper angles with each other. When, however, a piece of Iceland spar, or tourmaline, is employed, then these crystals produce the same result by double refraction only.

As a matter of convenience (although it involves expense), we should recommend those of our readers who can afford it, to purchase a Nicol's prism, which is merely a rhomb of Iceland spar, divided and rejoined in a wedge-like form, for the purpose of removing, as far as possible, the extraordinary and ordinary rays from each other. The angle of vision through it is of course always the same, its optical character having been attended to during its construction by the optician. It forms the best kind of analyser. It is also desirable that the student should possess two pieces of tourmaline, as they are the readiest means of observing several of the phenomena which we shall mention. In the absence of these, however, the simple apparatus we have named will answer the purpose; and will have also the advantage of calling out both the skill, patience, and close attention of the inquirer.

If pieces of mica, of varying thickness, are interposed between the analyser and the polariser, they will present appearances of colour which vary according to the thickness of the substance. Those comparatively thick afford red; and the thinner kinds give tints of various shades of blue: all the intermediate colours of the spectrum, and their numerous combinations, being thus obtained, their complementaries come in view on the analyser being moved through an angle of 90° with its previous position in reference to the polariser. If, however, the mica be slightly shifted, the play of colours will be continually varied; because other planes or laminæ come within the line of view.

Now these colours correspond in all respects as to order, &c. (excepting the thickness of plates producing them), with those obtained by means of a lens pressed on glass, the prism, the soap-bubble, &c., on which we have already dilated.‡ Their immediate cause, however, is polarisation; whilst those we have referred to previously, are the result of interferences, produced either by simple reflection or refraction. However, the doctrine of the interference of light, is equally applicable to that which has been polarised as to light in its ordinary state; and pursuing the plan we have hitherto adopted, we shall now only refer to our remarks on interference,§ leaving our readers to extend such in their application to the subject with which we are now dealing. The experimental proofs and mathematical investigations which would be required to fully elucidate this subject of polarised interference, are at once too delicate and abstruse for most of those for whom our work is intended. The advanced physicist may consult, with advantage, papers by Fresnel, Arago, Herschel, and others; of which we regret to say that no general synopsis exists—a fact partly due to the narrow limits in which the study of the subject is confined by its abstract character; and on account of the necessity of high mathematical attainments on the part of those who would fully investigate it.

We shall now pass on to consider some magnificent appearances which certain substances present when examined by means of polarised light: but, before doing so, we may just name, that the coloured phenomena to which we have just alluded may be obtained in selenite, the yellow prussiate of potass, &c.; all of which, like mica, vary in the tints they produce, in proportion to their thickness. Selenite, which is a crystallised form of sulphate of lime (plaster of Paris), is frequently arranged in the form of animals, church windows, &c.; and this affords a pleasing and popular illustration of polarised light and its effects.

Referring to our remarks at a previous page,‖ whilst speaking of double refraction and optic axes, we noticed that some crystals are uniaxial, and others biaxial. The latter class, when viewed under the polariscope, presents some interesting phenomena, and of a kind to which there is found no analogy in any other department of physical science.

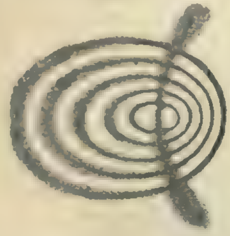
‖ *Ante*, p. 79.

If a piece of mica be placed close to the analyser, and carefully examined, a proper specimen will present two black spots, round which extend five series of rings, of the most beautiful colours. These are best seen by means of a tourmaline plate; but the simple apparatus which we have described answers the same purpose. An addition of an eye-piece, which Mr. Bestall has made to his polariscope at our suggestion, shows these fine effects exceedingly well.

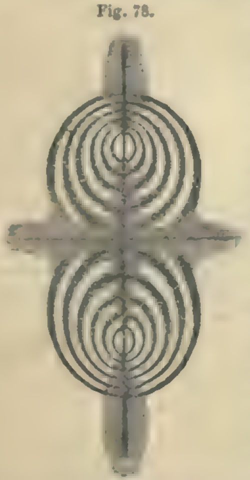
In the centre of the rings, the black spot indicates the position of the optic axes of the mica;* and besides the rings and spots, a curved line, cutting the oval rings, may be observed. The annexed engraving gives a very faint idea of the beauty of these effects; each of the curves, of course, being coloured exactly like the Newtonian rings, but far exceeding them in size. A similar effect is observed at both axes; and if the plate be revolved round its centre, the curved band will assume a longitudinal appearance.

Fig. 77.



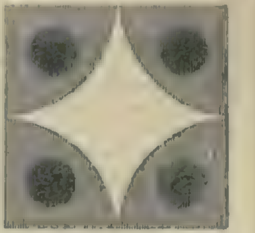
Nitre, which is also a biaxial crystal, exhibits this phenomenon in a more perfect manner, because the axes of its two crystals are close to each other. A perfect crystal is to be chosen, and a section made of it at right angles to its length, and of about the thickness of a sixth part of an inch. On this being polished, and examined in the polariscope, the appearances presented are exceedingly beautiful. The two axes, rings, &c., are nearer together than in the case of mica; and their appearance is represented in the annexed engraving, together with a cross, which extends between the two axes. The cross may be made to assume various positions, by causing the piece of nitre to revolve between the analyser and the polariser, on the geometrical axis of the crystal. Particular attention is required to the polish, thickness, and other points. This, and many other crystals, however, may be purchased, ready mounted, of the opticians. Amongst such, we may mention Iceland spar, which presents a very fine appearance when of proper thickness.

Fig. 78.



Some very beautiful effects are observed when unannealed glass is viewed in the polariscope. In our early remarks on the influence of the molecular constitution of a mass on a ray of light passing through it, we stated, that many differences could be noticed, by aid of polarised light, which are entirely unperceived by common light. Glass, whose parts are homogeneous, shows no effects; if, however, such is suddenly heated or cooled, then its constitution is altered, and colour, &c., may be perceived therein. A piece of glass, a quarter of an inch thick, and an inch and a-half square, if suddenly cooled from the liquid mass, presents a very pretty effect if placed some distance from the analyser. This is represented in the following engraving, which but crudely illustrates the beautiful results produced. In the piece from which we have drawn our cut, each of the circular parts are dots of a rich blue colour, separated by a white cross. The latter changes to a black cross, with reddish-orange dots, on revolving the analyser through 90°.

Fig. 79.



This singular appearance and effect has a very valuable application. In the manufacture of glass, the greatest care must be taken to have it properly annealed before it is introduced into commerce, if the manufacturer has the least regard to his own character or the interests of his customers. These considerations, however, have very little weight with those whose consciences are in the inverse ratio of their love of money; and hence an immense quantity of glass vessels are annually manufactured and sold, which, for the ordinary purposes of life, are utterly valueless. This arises from the fact that they are badly annealed. The process of annealing is intended to render glass less liable to break on being subjected to sudden variations of temperature; and is effected by first submitting the vessels to a great heat, and then allowing them to cool very gradually. Glass, like steel, may thus be rendered more fit for daily use; and, indeed, annealing and tempering are similar processes, and produce similar results. Well-annealed glass produces none of the appearances we have been describing; whilst unannealed readily answers that purpose. If, therefore, any suspected glass vessel, lens, &c., be examined by the polariscope, its character may at once be ascertained. This fact is of considerable use in daily life. To the philosopher it affords a means of testing the nature of the glass of which his lenses and chemical apparatus are made. To our housewives we may equally offer the use of the polariscope in the purchase of glass vessels of any kind; and a judicious application of the principles we have laid down, may have the double effect of preventing annoyance by the sudden fracture of badly annealed vessels, and an infraction on that patience of which, it is said, the fairer sex are the chief possessors.

CIRCULAR POLARISATION.

Our remarks have hitherto been confined to that kind of polarisation which takes place in certain planes existing between the axes of any objects and the direction of the polarised ray. We proceed now to notice briefly some phenomena which are presented by solids and liquids, in which we shall find that the effects depend on a rotation, right or left respectively, between the axis of the body and the direction of the polarised light. A plate or section of rock-crystal is an object which presents this peculiarity to the eye of the observer. This is cut perpendicularly to its axis of refraction; and it affords, when viewed by means of an analyser (which may be a Nicol's prism), the appearance of rings round its axes, the colours of which change according to the direction in which the analyser is moved. The colours succeed each other in regular order, just as we find them presented by the prism:† and supposing the analyser to be turned towards the RIGHT hand, then red, orange, yellow, green, blue, and violet, successively appear; and such bodies have what is called RIGHT-handed polarisation: if, however, these colours succeed each other in any body when the analyser is turned towards the LEFT hand, then such is said to have a LEFT-handed polarisation.

It may be as well, before we proceed further, to state, that an ordinary polarising plate, and a Nicol's prism, will answer well for solid transparent bodies, such as rock-crystal, starch, &c.; but for fluids (of which we shall presently speak), an arrangement is required of a form suitable for the purpose; one of which is represented in the following engraving, and of the best form we have tried.

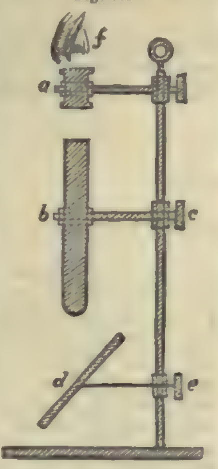
In Fig. 80, *a* represents a Nicol's prism, fixed, by means of a ring and screw, on a common ring-stand; *b* is a tube in which the liquid is placed, which may be partly covered with black paper, to keep out

---

* See *ante*, p. 79.

† See *ante*, p. 41.

Fig. 80.



extraneous rays. These tubes must be of various lengths, to suit the different liquids which may be employed; and they are held upright between the eyepiece and the polariser, by means of a ring, which is again attached, by the screw, *c*, to the ring-stand: *d* is an ordinary polarising plate, attached to the stand by the screw, *e*; and *f* is the eye of the observer. We need scarcely state, that the analyser must so rest in its socket, as to be readily turned round through the circular ring, as by means of its rotation over the tube, *b*, the phenomena are observed. In complete instruments, *a* rests in a graduated frame, which is essential for accurate experiments, because the angle of rotation varies for each liquid examined; and their differences, with respect to polarised light, are so pointed out. The bottom of the tube, *b*, should be as flat as possible, so as to prevent the loss of light on account of its external curvature. With such an apparatus, which is easily constructed, the student will have a wide field for research. He will be enabled to detect physical characteristics in bodies which no other means can point out; his ideas in reference to the constitution of such will be extended; and from merely examining the external peculiarities of the various substances presented to him, he will be able, as it were, to acquaint himself with their internal constitution, in a manner as astonishing as it is instructive.

We may here shortly point out the essential difference which exists between plane and circular polarisation. In the former, the chief effects are witnessed when the planes of observation are at *right* angles to each other. In circular polarisation these angles vary, and depend on circumstances, which, in their turn, arise directly from the peculiar or individual constitution of the body under examination. We should remark, that the best plan of observing the phenomena of circular polarisation, is that of using homogeneous or single-coloured light;[*] and this is easily managed by interposing a plate of red glass between the eye and the analysing prism. This prevents a variety of disturbing causes; and it also ensures the disappearance of the extraordinary ray.[†]

We may mention, that some little difficulty occurs to the beginner in observing the direction of rotation; because, as we have just stated, different liquids require greater lengths before the phenomenon is exhibited. The following, however, we may adduce respectively, as instances in which the effects may be observed; and, as they have all been tried in an equal length of tube—namely, in one of about six inches—they will afford a starting-point, from which the student may commence his progress. We have also given the angle, as indicated by the index on the analyser, which completes the arc of rotation for each.

Possessing Left-handed Polarisation.	
Oil of turpentine	45°
Naphtha	12° 40′
Possessing Right-handed Polarisation.	
Oil of bergamot	29°
Weak solution of cane sugar in water .	23° 5′
„ „ of milk „ „ „ .	10° 3′

It will thus be observed, that the angle of the arc of rotation, and its direction, become definite physical characteristics of the various bodies in solution to which we may apply the test of polarised light. These researches have been of the greatest advantage to the chemist as a means of analysis; and, as such, we cannot too highly value the results which have been obtained. We must, however, defer entering fully into the consideration of these interesting facts, to our section on Chemistry, in which we shall more completely show their special applications.

If our space, and the character of our work permitted, we might examine a great variety of subjects incidentally connected with, or elucidating, the phenomena of polarisation. Some of these we shall have to consider when we deal with what we may term the Magnetic Relations of Light. Others will come under our notice, under the sections of Mineralogy and Crystallography; and, as such, we shall have a better opportunity of dealing individually with special cases, than we have at the present time, whilst endeavouring to lay down and illustrate laws which have a general rather than a particular application.

Before concluding, however, our remarks on the Polarisation of Light, we may refer our readers again to the analogy which exists between the same phenomena in connexion with heat. The observations we made previously,[‡] will have prepared the student for the more complex phenomena of luminous over calorific rays; and what we have just finished discussing, will, in a similar manner, elucidate and extend the doctrines of calorific refraction. We may also add, that the analogies of the two forces of heat and light, thus seem, at each step, to converge together; and, like the vanishing points in a landscape, their differences seem to grow less in proportion as our view of them becomes more extended and comprehensive.

As we here must end our examination into the laws of light, we may remind the student, that many of the facts we have been investigating will again require our attention when we inquire into the phenomena produced by electricity, magnetism, dia-magnetism, and sound. Each of the forces ranked under the term "undulatory," has necessarily a mutual connection. In fact, they sometimes seem as if one force, modified by special circumstances, or the affections of matter, would satisfy the conditions implied in what we now recognise as so many separate and independent agents.

We have already seen how far heat and light are similarly subject to the same results when undergoing reflection, refraction, and polarisation. We shall find that sound is partly subject to the same influences; and that electricity and magnetism have a connection with both the agents to which we have already directed attention.

The attentive reader and student will reap great advantage in following, as closely as possible, the various relations in which these questions stand to each other. The nature of our plan forbids our entering into minute detail; but the student can, at his leisure, ponder over and collect these analogies, and thereby he will find that each subject and section, as we proceed, will form a kind of exposition to others. One of the greatest benefits, in an intellectual point of view, which attends the study of experimental science, is its tendency to expand our powers of generalisation. By giving us a broad and expansive view of creation in general, we are insensibly raised above that narrow individuality of character which is so natural to us all. Whilst we mentally roam through the vast expanse of truth, we become enlarged in our ideas, chastened in our imagination, and strengthened in our reasoning powers.

Having thus considered the chief laws of light, we now proceed to some of its applications, in which we shall find the theories already explained put more or less into practical purposes. In these branches of our subject, the reader will not fail to notice how much more rapidly improvements in matters of daily life take place, when under the fostering guide of sound science, than under the uncertain *dicta* of crude and ancient empiricism. Yet we find that, although much progress has been made in many manufactures by men utterly ignorant of scientific laws—still such persons, generally speaking, gradually acquire an amount of information which is a partial substitute for sounder acquirements. Of this fact, many instances might be quoted; such as the production of the Tyrian purple, the staining of ancient glass and porcelain, &c. We may, however, possibly err in our notions with respect to the state of science in the early ages. But few works of those times have been handed down; and the destruction of the Alexandrian library, may have entirely shut from our view the results of investigations which might possibly have rivalled the productions of our own age. Whilst, therefore, we may rejoice in that which we possess, we should do so with modesty; for as long as science is studied, we shall ever have to acknowledge, that some of the ancients—Euclid and his co-workers—have done more to assist us in the means of pursuing exact investigations, than any of their successors.

CHAPTER III.

ARTIFICIAL ILLUMINATION.

We shall now proceed to consider some of the applications of light, commencing with that of Artificial Illumination; a paper on which has been furnished by a gentleman highly conversant with the subject.[*]

After the article on Artificial Illumination, we shall direct the attention of our readers to the interesting subject of Photography; and endeavour to put them in possession of both the practice and theory of that singular application of light.

ARTIFICIAL ILLUMINATION.

Historical Notice.—The advantages of artificial light are so numerous and important, that they must have claimed attention from the very earliest period of history: in fact, long before man had commenced his work of civilisation, the light of the cheerful fire must have been a source of comfort and security; for, perhaps, nothing assists so powerfully in dispelling the gloom of darkness, and banishing the terrors of night, as the lustre of a cheerful fire. And then, as civilisation advanced, the usefulness of artificial light must have been perceived in a thousand ways. True, it might at first have been employed merely as a luxury among the rich; but, in process of time, it became a necessary even with the poor; and were we now to deprive man of all means of obtaining artificial light, the consequences would be terrible—we should cripple his energies and impoverish his intellect—a great portion of his time would be lost to him—every industrial occupation would be hindered—the very safety of the community would be endangered—and, in fact, the wealth and commerce of every nation would be seriously affected. These considerations endow our subject with an interest of no ordinary character; and we may truly say, that few inquiries would furnish so profitable a result as a complete history of Domestic Illumination, "tracing its gradual development from the solitary watch-lantern, graven on the pyramid, through the graceful but very imperfect lamps of the Greek and Roman period, as exhibited in our museums, and the clumsy contrivances of the middle ages, up to the productions of modern times, satisfying the demands both of taste and science. In such a narrative might be shown the progress of light, in the literal signification of the word, by a careful examination of the various forms in which it has been at different times employed —as lamp, lantern, torch, flambeau, falot or cresset, candle, and gas—whether for the celebration of religious ceremonies, for increasing domestic comfort, adding to the security of the streets, or forming a beacon to guide the mariner at night. It would be, at the same time, a history glancing at the advancement which the improvements in illumination have given to the social condition of mankind, and at the advantages which science has derived from the study of this subject." Besides which, there would be mixed up with such an historical account many of the fanciful hypotheses and highly poetical conceits in respect of the nature of fire, which have at various times occupied the attention of man.

Perhaps the earliest source of artificial light was the wood fire, blazing in the recesses of the forest, or in the hut of the savage; and then, as experience led to the discovery of the fact that different kinds of wood burn with different degrees of splendour, it must have been perceived that certain vegetable substances might be employed, in preference to others, as a means of obtaining light. In this way a splinter of pine, the resinous bark of a tree, or even the oily kernel of a nut, might early have been resorted to for such a purpose; indeed, we are told that the inhabitants of Tortuga had long used the wood of yellow sandal; those of New England made choice of a resinous splinter of pine; the natives of British Guiana selected the wood of an amyris; and in Otaheite, the candle was a row of nuts fastened upon a skewer. Again, accident must soon have taught mankind that the resinous exudations of trees, the fat of animals, and the bitumen and naphtha of the mineral kingdom, were not only highly combustible, but that, while burning, they were also highly luminous. Having learnt this fact, it required but little ingenuity to suggest the use of some porous material upon which the combustible might be smeared, or into which it might be dipped, before it was burnt. In this way the torch, the candle, and the lamp, were doubtless invented.

The first authentic evidence that we have of the use of candles is furnished by Pliny in the 13th Book of his *Natural History.* He there says, in speaking of the lost books of Numa, that when Terentius, the scribe, discovered the sepulchre of the king, he found in it a parcel of books tied round in every way with *candles*, after the manner of the cere-cloth. This story is quoted from Piso, Tuditanus, Varro, Antias, and others: it is also repeated by Livy, who states that the candles were two in number. Now as Numa was the successor of Romulus, and reigned about 700 years before the birth of Christ, it is evident that candles were used in the earliest days of Roman history: judging, also, from the use to which they had been put, it would appear that they were composed of string or rope covered with some combustible, perhaps pitch or wax. It is to be regretted, however, that Pliny has not given us a more particular account of the construction of those candles; indeed, he has not informed us how any of the candles of his time were manufactured; he merely alludes to the subject incidentally. Thus, in his chapter on Willows, he says that the pith of the brittle rushes, which grow in marshy places, is used for making wicks for watch-candles and funeral-lights, to burn by a dead body while it lieth above the ground; and, in a subsequent chapter on Flax, he states that the part of the reed which is outermost and nearest to the peel, or rind, is called tow, and is good for nothing but to make lamp-match or candle-wick: nothing whatever being said respecting the material which was put about those wicks. The inference, however, is that the watch-candles in Pliny's time were like our rushlights, and that the others were similar to the pitched rope which we employ, after the fashion of a torch, for common illuminating purposes. Fosbrooke informs us, in his *Encyclopædia of Antiquities*, that the candles of the ancients were sometimes made of the leaves of the papyrus covered with wax or tallow: and he remarks, that common kitchen-stuff was used for such purposes as far back as the days of Augustine. A proof of this is to be found in the writings of Apuleius, who speaks of two kinds of candles—namely, the *cerei*, or wax, and the *sebacei*, or tallow.

During the middle ages, wax was extensively employed for purposes of illumination; and, according to Fosbrooke, the candles were not made by regular craftsmen, but by the monks, and the servants of the nobility. An illustration of this is to be found in Asser's *Annals*, where an account is given of the manner in which King Alfred directed his candles to be formed. "He commanded his chaplain to supply wax in sufficient quantity; and he caused it to be weighed in such a manner, that when there was so much of it as would equal the weight of seventy-two pence, he caused the chaplain to make six candles thereof, each of equal length, so that each candle might have twelve divisions marked across it." These candles, when burnt in succession, lasted for twenty-four hours, and each division indicated the third of an hour.

---

[*] As some of the facts included in the original have been already discussed, the editor has omitted such, and has made additions on matters which have come under his own observation.

Up to that time, the use of candles was chiefly confined to the churches, the monasteries, and the houses of the nobility; but in the 15th century the employment of candles had become very general; and the trade of making them had acquired so much importance, that the chandlers of London had obtained an act of incorporation. The candles of those days were all made by dipping the wick into the melted wax or tallow; but in the 18th century, the Sieur de Brez of Paris invented the plan which is now practised, of casting them in metal moulds; and, later still, the wax candles were made by rolling the wax around the wick. All subsequent improvements in the manufacture of candles have resulted from the very elaborate investigations of Chévreul into the composition of fats; indeed, most of his results have been made the basis of the several patents of modern time; as, for example, those of Bolts, Frémy, De Milly, Gwynne, Wilson, and others.

Lamps are also contrivances of very ancient date. They are frequently mentioned in the sacred writings; and there can be no doubt that they were much better known and more generally used than candles. Clemens Alexandrinus, and Eusebius, ascribe their invention to the Egyptians; but it is rather a singular fact that they were not well known in Greece during the time of Homer—at least, he has not referred to them. In his story of Penelope, he says, as most classical scholars will remember, that the suitors of Penelope paid homage to her with torches and odoriferous wood laid in a brazier. Lamps, however, were common enough in Rome during the early period of her history. Pliny frequently refers to them, and even describes the oil and the wicks that were burnt in them. The cities of Herculaneum and Pompeii have furnished us with excellent examples of both the form and the material of ancient lamps. It would appear that at first they were made of baked clay (terra-cotta), and that the design was simple in the extreme—an oval or elongated vessel, having a lip at one end for the wick; but in process of time, as the habits of the Romans became more luxurious and expensive, the material was changed for gold, silver, or Corinthian brass, and the design became more complicated. These lamps were either suspended from the ceiling or arranged in rows on a stand or candelabrum, the designs of some of which are exceedingly beautiful. The light which they furnished must have been dim and unsteady, for the construction of the lamp was always the same—namely, a solid wick immersed in a vegetable oil. Pliny says that the inhabitants of Sicily burned a kind of bitumen, resembling an unctuous or oily liquor; and that they collected it from the surface of a spring in the territory of Agrigentum. In other cases the oil which they used was of vegetable origin: it was extracted from the fruits of castor or olive; and, in more recent times, animal fats were employed. This was the condition of things until a very modern period, when M. Argand, of Geneva, effected a complete change in the art of illumination. Every one is acquainted with the lamp that bears his name; the principle of which is, that the oil burns at a high temperature, with a plentiful supply of atmospheric air. This is accomplished by means of a hollow cylindrical wick, and a glass chimney which surrounds the flame. Few improvements of any practical importance have been made on this principle, notwithstanding that many contrivances have been originated, and various combustible liquids resorted to.

The history of street-lighting furnishes many examples of the slow progress with which the art of domestic illumination has advanced. At first, the only lights in the public highways were those of the cautious citizen, who deemed it prudent to make his nocturnal visits under the protection of a link, a flambeau, or a lantern. We are told that the streets of Rome, even in her palmiest days, rarely exhibited more than one or two lanterns, which were suspended over the baths and other places of public resort. Now and then they were illuminated for a festival, and sometimes the forum was lighted up for a midnight exhibition; but, with these few exceptions, the city was a city of darkness. In the 4th century, the streets of Antioch and Edessa were furnished with public lamps. Libanius, in his panegyric of the former, says—"The light of the sun is succeeded by other lights, which are far superior to the lamps lighted by the Egyptians on the festival of Minerva or Sais. The night with us differs from the day, only in the appearance of the light: and with regard to labour and employment, everything goes on well; for some work continually, while others laugh and amuse themselves with singing." This fact is confirmed by Jerome, who tells us of a serious dispute that was maintained for some hours in the streets of Antioch, between a disciple of Lucifer and one of the orthodox: he says that the dispute was kept up until the streets were lighted, and then the disputants spat in each other's face and retired. In the history of Jesue Stylites, we are informed that Eulogius, the governor of Edessa in Syria, ordered lamps to be kept burning in the streets during the night; and that he employed for that purpose a part of the oil which was before given to the churches and monasteries.

It is worthy of notice, however, that public illuminations, either on account of religious festivals or general rejoicings, were very common with the ancients, and are of great antiquity. Herodotus states that the Egyptians had a festival of much solemnity, during which lamps were placed before the houses, and kept burning throughout the night; the Jews, also, celebrated their *festum encæniorum* in like manner. According to Æschylus, it would appear that the Greeks had their nights of public rejoicing; and there can be no doubt that the Romans were continually in the habit of lighting up their streets with lamps and torches, whenever an event of public importance commanded their attention. In some instances these displays were wholly unpremeditated, as when an orator distinguished himself in the senate, or a soldier in the camp. Cicero was thus honoured when he defeated the conspiracy of Cataline; and many a Roman general has been encouraged in his march by a like display of public enthusiasm.

Until very recently, the modern cities of Europe were no better provided for in this respect than the ancient. It is true that statutes were made, and orders proclaimed, to the effect that every citizen should contribute his share to a system of general illumination. This was effected by placing a candle in each of the lower windows of the house, and keeping it burning, from nightfall to the hour of twelve. At first the performance of this duty was optional, but at last it became compulsory; nevertheless, it was at all times so sadly neglected, that the thief and the assassin had abundant opportunities for mischief. Paris was the first city to improve on this condition of things; for in the year 1558, huge contrivances, called *falots*, were erected in the principal thoroughfares. The *falot* was a sort of vase filled with pitch, resin, and such-like things, in a state of combustion; but it was soon found that this mode of lighting the streets was expensive, dangerous, and inconvenient, and consequently the *falot* was quickly displaced by the lantern, which was a rude frame covered with horn or varnished leather. For more than a hundred years this was the plan of illumination generally adopted; and, as may be supposed, the light was too feeble for any useful purpose: indeed, no one of importance ventured abroad after dark without his torch or flambeau. The latter, therefore, became so indispensable to the midnight traveller, that an ingenious Italian, named Laudati, conceived the idea of opening stalls for their hire. He started his business in Paris in the month of March, 1662; and he managed it so well that he obtained the entire monopoly of the whole city: his charge for a link was from three to five sous the quarter of an hour, according to the rank of his customer. In 1667, Nicholas de Reynio, the first lieutenant-general of police, introduced a still better system of street-lighting. He invented lamps of glass, which, from their resemblance to a bucket, were called *lanternes a seau*. These he fixed in the middle of the streets, exactly in the same way as they are now suspended in many parts of France, by means of ropes or wires fixed at each side of the street, the lamp being suspended in the centre.

We have no means of showing when London was first lighted with lamps; though Maitland says, in his *History of the Metropolis*, that an order was issued as early as the year 1414, commanding the inhabitants to hang out lanterns for the benefit of passers-by. This information is derived from Stow, who, in his *Survey of London*, remarks that, "in 1417, Sir Henry Barton, the mayor, ordained lanthorns with lights to be hanged out in the winter evenings, betwixt Hallontide and Candlemasse." It does not appear, however, that these orders were much attended to, for we find that they were repeated again and again over a period of three hundred years. At the expiration of that time the corporation of London determined on removing the service altogether out of the hands of the inhabitants; they, therefore, entered into contract with a person to set up the public lights, and to attend properly to them; for which they gave him permission to charge six shillings a-year to every householder whose annual rent exceeded ten pounds. In 1736, the lord mayor and common-council applied to parliament for power to light the streets in a better manner. This power was further increased in 1744; and, from that time, the illumination of the City has been gradually improving.

Most of the preceding facts have been derived from Beckmann, who tells us that the following are the dates when public lamps were introduced into the other cities of Europe:—Amsterdam, 1669; Hamburg, 1675; Copenhagen, 1681; Berlin, 1682; Hanover, 1696; Leipsic, 1702; Vienna, 1704; Dresden, 1705; Halle, 1728; Birmingham, 1783; Brunswick, 1765; Nantes and Versailles, 1777; Zurich, 1778; and Strasburg in the year following.

In very recent times the greatest of all improvements in street-lighting has been effected by the use of gas; and those who can remember the old-fashioned lamp, with its miserable glimmer, and the dangers which constantly beset the traveller after nightfall, will have no hesitation in saying that the employment of gas for illuminating purposes has been one of the most important events of modern time. In truth, it has not only been the means of effecting a wonderful change in the whole system of artificial illumination, but it has also produced an equally important change in the domestic concerns of the people: it has encouraged industry, developed the arts, protected property, diminished crime, and operated in a thousand ways as a medium of wealth, prosperity, and social improvement. All this has been accomplished in less than half a century; for Mr. Clegg tells us, in his work on gas-lighting, that he, in 1813, was the first to put gas into the lamps of Westminster; and he has also given us a graphic account of the fear and wonder with which it was contemplated. Now, however, it is one of the most familiar objects of daily life; for there are almost as many gas-lights in this metropolis as there are human individuals. What would Beckmann say of all this, if, in the year 1786, he imagined the lighting of London to be perfect, and thought that the appearance of the City, after dark, when seen from a distance, was noble and magnificent! Of a verity, his admiration would be boundless. One thing, however, is still wanted to make gas the greatest boon of the 19th century—that is, a guarantee in respect of its purity and harmless qualities. Already the demand for these has become urgent; and it will not be long before the gas companies of England will find it to their advantage to yield to it. In fact, the City of London has, as usual, taken the initiative in this matter, and has appointed an officer to test the quality of the gas supplied within its boundaries. The results are so important to the community, that all other cities and towns will, ere long, follow the example; and then we shall hope to see the art of domestic illumination made more perfect than it is at present.

ON COMBUSTION AND FLAME.

General Remarks.—Artificial light is due in almost every instance to chemical action—that is, to a rapid or energetic union of two or more substances, and the formation of new compounds. At one time it was thought that matter in the act of burning was destroyed, and thus the term combustion was used to designate the phenomena: but we now know that matter is indestructible, and that substances, while burning, merely change their form. In proof of this, it may be mentioned that the chemist is enabled to ascertain the exact composition of an organic substance, by simply collecting and weighing the products of its combustion. This, indeed, constitutes the principle of every organic analysis.

Those substances which evolve light and heat during their chemical union, are generally distinguished by the terms "combustible" and "supporter"—the former term being applied to the body which burns, and the latter to that which permits of the burning. We speak, for example, of wood, tallow, and coal as combustibles, and of atmospheric air, oxygen, and chlorine as supporters; but a very little reflection will show that those expressions are altogether arbitrary, and that they might in most cases be reversed without destroying their sense. This will be clear from what follows. When coal gas is burnt in atmospheric air or oxygen, we call the gas the combustible, and the air or oxygen the supporter; but by changing this condition of things, and igniting a jet of air in a vessel of coal gas, we should then call the air the combustible, and the gas the supporter; from which it must be evident that the phenomena of combustion are due to a reciprocal play of affinities, in which one element takes as large a share as the other; and that the distinction of property, as implied by the terms combustible and supporter, is not founded on fact: nevertheless, we still continue to make use of those terms, because of the convenience they afford in description.

Theories of Combustion.—For a long time the phenomena of combustion were thought to be dependent on the evolution of a peculiar subtle principle, called *phlogiston*. This hypothesis was originated by Becher in the 17th century, but it was not elaborated until the days of Stahl, when it was universally accepted among chemists as the Phlogistic theory. For more than a hundred years the theory held a prominent place in the science of chemistry; and, although it was founded in error, or rather in a total misapprehension of facts, yet its truthfulness was not doubted until the time of Lavoisier, when, by an accurate examination of the facts, he exposed its fallacy. According to the Stahlian theory, there was something—namely, phlogiston—always given out during combustion, from which it might reasonably be inferred that the body became lighter; but, by collecting the burnt products, and weighing them, Lavoisier showed that it actually became heavier, and that something must, therefore, have been absorbed or taken in. This something he soon found was derived from the atmosphere, and was the gas just then discovered by Scheele and Priestly. Having determined those facts, and tested their truthfulness in every possible manner, he boldly advanced his new theory of combustion, the Antiphlogistic; in which he said that the phenomena of combustion were *at all times* due to the rapid chemical union of oxygen with a combustible. Had Lavoisier been content to say that the phenomena were *usually* dependent on such a combination, it is probable that his theory would have existed in a modified form until the present time; but, in his attempts to make it too general in its application, he effected its ruin; for, in the course of a few years, the investigations of Sir Humphry Davy into the properties and elementary nature of chlorine gas, demonstrated the fact, that combustion might be effected without the aid of oxygen at all. This was proved by the action of chlorine on antimony or copper; and, from that time, the phlogistic theories were put aside; and chemists have ever since regarded the phenomena in question, not as the result of any particular kind of combination, but merely as the energetic display of ordinary chemical action. And here we may remark, that there is not, perhaps, in the whole range of chemical science, a subject that offers so many interesting facts for contemplation, as that to which we have just alluded; for it teaches us that the progress of human knowledge is often dependent, not so much on the discovery of great and important truths, as on the manner in which they are contemplated; and if men's minds are not prepared for the reception of those truths, they will either be disregarded, or else made the means of propagating error. This was the case with the theory of Becher and Stahl, which had the effect of distorting every fact that came under its influence. In this way, for years, it delayed the progress of science, and checked the development of truth. History tells us, that for more than a century before the discoveries of Lavoisier, the main facts of his investigations were broadly set forth in the writings of Hooke and Mayew; but from the circumstance that those facts were premature—that men's minds were not prepared to receive them, and that chemists were infatuated and led astray by the false doctrines of Becher and Stahl—the more humble but important truths of Hooke and Mayew were allowed to pass unnoticed; and they lay dormant for more than a hundred years.

Manner in which Combustion may go on.—An examination of this question will show that most substances have the power of burning in three ways; namely, by slow oxydation, when little or no light is evolved; by a more rapid combination, when the burning becomes so hot as to render itself luminous; and by a still more energetic action when it bursts into flame. We have examples of the first of these processes in the phenomena termed *Eremacausis*, or slow burning, as is witnessed in the glowing of phosphorus, and in the luminosity of decaying wood or putrefying fish. In most of these cases, the heat and light evolved at any given moment are not very considerable; and few persons would be disposed to regard the phenomena as those of combustion; but when it becomes known that the total amount of heat, and perhaps also of light, generated during this slow kind of oxydation, is exactly the same as that evolved during the most rapid combustion of the same substances, there will be no difficulty in understanding that the phenomena in the two cases are referable to the same kind of chemical action, and belong to the same category.

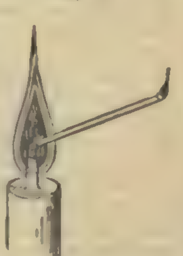
The second mode of combustion is observed when coal gas, or the vapour of ether, alcohol, or wood-spirit, is mixed with air, and brought under the influence of spongy platinum or fine platinum wire. This is best effected by suspending a coil of the wire in the flame of either of the combustibles, then blowing the flame out, and allowing the vapour or gas to play on the surface of the metal: in this way the platinum will keep up the combustion, and will continue to glow, although the vapour or gas will not be inflamed.

The third kind of combustion is produced whenever a sufficiently high temperature is applied to any kind of vaporous matter so as to inflame it. The temperature at which this is effected varies with different combustibles; some take fire at ordinary temperatures, as finely-divided phosphorus, and phosphuretted hydrogen; whereas, solid or massive phosphorus requires a temperature of 140° to inflame it; sulphur takes fire at about 500°; hydrogen and carbonic oxide at 1000° (which is a red-heat); and coal gas, ether, turpentine, alcohol, oil, tallow, and wood, at about 2000° (or an incipient white-heat); but when once inflamed, they all continue to burn at a very exalted temperature.

The Nature of Flame.—The preceding remarks will be sufficient to show that flame is nothing more than gaseous matter burning at a very high temperature. We may prove this by experiment. If we take a coil of iron wire, or a piece of watch-spring, arm it at one end with a fragment of burning wood, and then introduce it into a jar of oxygen gas, the metal will take fire and burn with the most brilliant scintillations, but it will not produce flame. Again, if we expose wood to the action of heat in a closed vessel, so as to drive off all volatile matters and obtain its fixed solid constituent, charcoal, we may burn it in an atmosphere of oxygen without producing flame. In both of these examples, the absence of flame is entirely due to the absence of gaseous matter in the combustibles; and to show that a high temperature is necessary to produce flame, we have only to burn coal gas, alcohol, ether, or wood-spirit, at the low temperature of glowing platinum, and they will not inflame.

It may be thought, perhaps, that in the case of wood, tallow, oil, phosphorus, &c., the flame cannot result from gaseous matter, because those bodies are either solid or liquid in their nature; but a little consideration will teach us, that, in the act of burning, they all become converted into gases or vapours. This may be easily demonstrated in the case of a common candle or oil-lamp, the wick of which conveys the fluid combustible to the flame, where it is decomposed and converted into vapour. Now, if we hold a small glass tube, or even a piece of tobacco-pipe, in the flame of the candle, so that the end of the tube shall be exactly over, and almost in contact with, the top of the wick, it will collect the combustible vapour and convey it out of the flame, whence it may be burnt by applying a light to the opposite end of the tube (Fig. 81). This experiment also proves that flame is hollow: it consists, in fact, of three cones placed one over the other. The inner cone, which is of a dark colour, and surrounds the wick, is formed by the vapour of the decomposed tallow. The second cone is the luminous one; it envelops the preceding on all sides, and consists of the ignited particles of the gas making its way outwards to the air. The third, or outermost cone, is nearly invisible; it constitutes that pale blue film which everywhere surrounds the luminous part of the flame. We may make this cone more evident by bringing a piece of thread moistened with salt into the lower edge of the flame, when the cone will be instantly lighted up with a deep yellow tinge. Another mode of discovering it is to screen off the luminous cone by means of the hand; or it may be rendered visible by intersecting the flame with a piece of fine platinum wire, or wire gauze, the ignition of which discovers the exact boundary of the cone. This cone is made up of gas in an actual state of combustion; for it is here, and here only, that the process of oxydation is rapidly going on.

Fig. 81



Cause of Light in Flame.—A little experience will inform us that different combustible substances burn with different degrees of intensity (Fig. 82). We will endeavour to show that this is wholly dependent on the number of solid particles that are ignited within the flame. If we take a jet of hydrogen gas and fire it, or make use of a flame of alcohol from a common spirit lamp, we shall notice that neither of these bodies burn with any great amount of light; the case is very different, however, with a candle, or even with a jet of coal gas. Now, in the former examples the hydrogen and the spirit do not contain any solid particles, and consequently do not contain any species of matter that can, by its ignition, evolve light: but in the latter examples

Fig. 82.

the case is very different; for by intersecting the flame with a cold plate, we shall find that there are myriads of solid particles in the form of soot, which, by their ignition, produce that intensity of light for which such combustibles are valued. Again, when sulphur is burnt in oxygen gas it evolves a faint blue spectral light, that is hardly sufficient to illuminate the dial of a watch; but when phosphorus is treated in this manner, it emits a volume of light that rivals in intensity that of the sun. It will be noticed that the products of the former are wanting in solid particles, whereas those of the latter are made up of myriads of white flakes of solid phosphoric acid. It is on this account that carbonic oxide and wood-spirit, as well as hydrogen, sulphur, and alcohol, burn with little or no light; while zinc, antimony, ether, turpentine, oil, tallow, and coal gas, burn with more or less splendour. But we may communicate a great degree of brilliancy to some of the former, by giving them a large proportion of solid particles; for example, when we sift a little magnesia into a jet of hydrogen, its illuminating power is at once raised to a high standard; and the same thing happens if we employ lime, oxide of zinc, or white antimony, instead of the magnesia. So, also, if we naphthalise the gas by passing it through a chamber containing ether, turpentine, benzole, or coal naphtha, its light is increased to that of the best description of coal gas. In fact, coal gas consists, in great part, of hydrogen and carburetted hydrogen; both of which are, as it were, naphthalised with other compounds that give it illuminating power. But the most striking example that we can refer to in illustration of the fact that the light of flame is dependent on the presence of solid particles, is afforded by the results obtained with the oxy-hydrogen blowpipe.* When the flame of the mixed oxygen and hydrogen gases is seen as it issues from the jet without impinging on any solid substance, it strikes the observer as being an insignificant and almost invisible object; but directly it is thrown on a piece of lime or other material that will give it solid particles, it instantly becomes one of the most splendid lights with which we are acquainted: in fact, the intensity of the oxy-hydrogen light is so great, that when its rays are reflected by means of a concave mirror, they are distinctly visible at a distance of sixty-eight miles. We can easily understand, therefore, why it was so earnestly proposed by Lieutenant Drummond, as a means of illuminating lighthouses. So, again, with the electric light, the brilliancy of which is dependent on a number of minute particles of charcoal that are intensely heated by the galvanic current. The splendour of this light is scarcely inferior to that of the sun; for, on one occasion when it was tested, it was found to be equal to that of 300,000 wax candles, and was distinctly seen at a distance of several miles.

Lastly, it may be stated, as the converse of the preceding, that we can always reduce the illuminating power of flame by diminishing the amount of solid material contained in it. To take coal gas, by way of example, we shall find that the light may be kept down, or even destroyed altogether, by blowing atmospheric air into it. This sometimes happens with the lights in the streets, and then the flame is reduced to an insignificant blue flicker. The same thing occurs if we mix atmospheric air with the gas before it is consumed, or if we employ a glass chimney that is too tall for the size of the flame. In all these instances, the solid particles of charcoal contained in the gas are burnt too speedily, and, consequently, there is no time for their previous ignition. This teaches us that there is one great point always to be attended to in the management of gas for illuminating purposes: we should take care that the supply of atmospheric air is so regulated that, on the one hand, the solid particles shall not be instantly consumed; and, on the other, that they shall not escape as uncombined soot. Many gas-burners are constructed so as to effect this of themselves; this is the case with the fish-tail and the bat's-wing, which present a thin stratum of flame for the action of atmospheric oxygen. Other burners, as the Argand and its modifications, require a glass or chimney for the purpose of regulating a proper supply of air. The chimney acts by creating a draught, and so causing the air to play into the body of the flame; but, if the chimney be too high, the draught will be too great, and the gas will be overburnt; whereas, if it be too low, the current of air will not be sufficiently strong, and the carbon of the gas will escape in the form of soot or smoke. As a rule, the flame should be kept at about one inch below the top of the chimney. Mr. Billow, of London, has contrived a burner, which not only demonstrates the nature of flame, and the cause of its light, but also shows the effects of an under supply of atmospheric air. In ordinary burners the air is admitted to the flame on all sides, and it even passes up into its interior; but in the burner contrived by Mr. Billow, the inner supply of atmospheric air is cut off, and, consequently, the gas is but imperfectly consumed. The result of this is that carbon is liberated, and, by the construction of the burner, it is made to gyrate round and round, until it collects into little solid masses, which fall by reason of their own weight: directly this happens they come into contact with a part of the flame where combustion is actively going on, and they are instantly projected into the atmosphere like so many diminutive rockets.†

Quantity and Intensity of Flame.—It must have been noticed again and again, by those who are in the habit of pursuing their avocations by the aid of artificial light, that there is a great difference in the practical value of different kinds of illuminating agents: for example, the eye is often most painfully excited with the strong glare of certain varieties of light, although there is not enough of it to produce the necessary illumination of surrounding objects; on the other hand, we sometimes perceive that the light is particularly inoffensive, notwithstanding that everything about us is brightly and sufficiently illuminated. It is probable that these two conditions are entirely dependent on two states of light, which have not yet been properly appreciated. To the one we apply the term *intensity*, and to the other *quantity*. We have examples of the former in the electric light, in the Drummond light, and in the vivid combustion which is going on in the burners of Leslie and Wingfield; of the latter in the diffused light of day, and in the illumination that is produced by a number of separated gas jets. In the one case we have comparatively few solid particles, but they are heated to a high degree of intensity; in the other we have a much larger number of ignited points, but their ignition is not carried to so high a temperature. These facts have not yet received so much attention as they deserve; and in all our endeavours to improve the quality of a burner, we should never lose sight of the fact, that the human eye requires far more of quantity than it does of intensity for agreeable vision.

The Colour of Flame.—Our preceding remarks have gone to show that the light of flame is dependent on the *number* of solid particles present in it: we will now demonstrate that the colour of the light is dependent on the *nature* of those particles. The flame of alcohol or wood-spirit is naturally colourless; but we may give it various tints by saturating the spirit with different kinds of saline substances. Chloride of potassium will make it violet; boracic acid or chloride of barium, green; chloride of copper, blue; common salt, yellow; chloride of strontium, red; and chloride of lithium makes it of a carmine tint. The same substances produce a similar effect when they are sifted into the flame of hydrogen; and the pyrotechnist relies upon these properties in producing the various coloured devices which are the glory of his art. Some years ago there was an exhibition in London of philosophical fireworks; and it was described at the time as a very great novelty. It was said to be effected by the combustion of gases charged with various substances, and ignited from jets arranged in different forms, as spirals, wheels, stars, &c., the tints being chiefly red, blue, green, and purple. It is not known what were the materials used; but from the strong smell of ether and spirit in the room, there is no doubt that these liquids were among the constituents of the gases, and that they were employed as the solvents of different saline compounds; in fact, the chromatic cloud which used to attract so much attention a few years since, was nothing more than the burning vapour of spirit charged with the above-named salts.

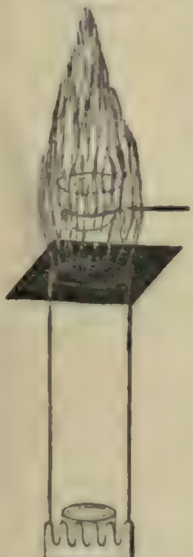
† Our readers will find a description of this burner at page 257 of the second volume of the *Journal of Gas-Lighting*.

Fig. 83.



The Heat of Flame.—Under ordinary circumstances, the combustion of gaseous matter takes place only at the exterior of a flame—that is, where the surface of the luminous cone is in immediate contact with the atmosphere; but we may increase these points of contact, and therefore the combustion and heat, by throwing air into the interior of the flame, or by mixing the combustible with the atmosphere before it is burnt. In this way we can increase the heat of flame to almost any extent; indeed, the principle of the common blowpipe, of which there are numerous varieties, is founded on this fact; and if we blow a jet of oxygen into a flame of coal gas by means of a double tube, we obtain a temperature that is sufficiently high to melt platinum. A mixture of air and coal gas may also be burnt over a chimney covered with wire gauze, and then the heat produced is sufficient to keep a small crucible at a bright red-heat (Fig. 83); but the highest temperature of all is generated by the combustion of a mixture of two parts, by measure, of hydrogen gas, and one of oxygen. This constitutes the mixture of the oxy-hydrogen blowpipe, which has been so useful an instrument in the hands of the chemist. Different combustible substances do not, however, produce the same amount of heat, or consume the same relative proportion of oxygen. This is an important fact, and it should always be remembered in considering the effect produced by different illuminating agents in the atmosphere of the room in which they are burnt. The following table exhibits, in approximate numbers, the relative values of different combustibles in this respect:—

Name of Combustible.	Weight of Water raised 1° by 1 of body.	Weight of Oxygen consumed by 1 of body.	Weight of Carbonic Acid produced by 1 of body.
Carbonic oxide	3650	0·57	1·57
Cyanogen gas	9380	1·23	1·70
Olefiant gas	21630	3·41	3·14
Marsh gas	23610	4·00	2·75
Hydrogen gas	61230	8·00	0·00
Wood-spirit	9930	1·50	1·37
Alcohol	12630	2·09	1·87
Rape oil	16770	2·89	2·81
Sperm oil	16950	2·90	2·82
Olive oil	17130	2·90	2·82
Turpentine	19110	3·29	3·27
Tallow	14430	2·90	2·91
Wax	16230	3·00	2·92
Spermaceti	17130	3·10	3·00
Sulphur	4530	1·00	
Phosphorus	10830	1·25	

Coal gas is chiefly composed of hydrogen and light carburetted hydrogen, with which there is a small proportion of olefiant gas; it therefore evolves enough heat to raise about forty thousand times its weight of water one degree, and it produces about twice its weight of carbonic acid.

In order to show the advantage of well-purified coal gas over all other materials for artificial illumination, as regards the injury done to the atmosphere of the room in which their combustion is going on, Dr. Frankland has given the following table, which exhibits the amount of carbonic acid produced by a number of illuminating agents, burnt in such quantity as to give a light, for ten hours, equal to that of twenty sperm candles, each consuming 120 grains per hour:—

Tallow	10·1	cubic feet.
Wax	8·3	,,
Spermaceti	8·3	,,
Sperm oil	6·4	,,
Common London gas	5·0	,,
Manchester gas	4·0	,,
London cannel gas	3·0	,,
Hydro-carbon gas, with Boghead coal gas	2·6	,,
Hydro-carbon gas, with Lesmahago coal gas	2·3	,,

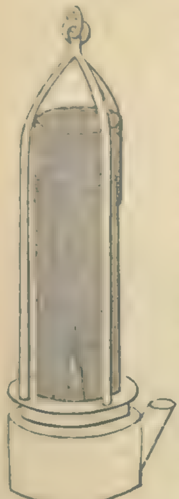
The Products of Combustion.—One of these—namely, carbonic acid—has been noticed in the preceding table; the other product of combustion is water. Occasionally there is also produced a small quantity of sulphurous acid; but, as a rule, it will be found that combustible substances are composed of only carbon, hydrogen, and oxygen. Coal gas, however, contains a small proportion of bisulphuret of carbon, and sometimes a very perceptible quantity of sulphuretted hydrogen, both of which, in burning, produce sulphurous acid—the acid of the burning match; and this, by further oxydation of the air, becomes sulphuric acid, or oil of vitriol, a product which has been found to exert the most destructive influence on textile fabrics, as the covers of books, &c. Again, when coal gas is not perfectly consumed, it generates aldehyde, volatile oil, and a few other compounds which are exceedingly offensive.* This is experienced in every kind of gas-stove, where the flame is allowed to play on a large cooling or radiating surface; and hence it is advisable that gas should always be burnt in such a manner that the products of combustion may easily escape into the external atmosphere. Other illuminating agents, as tallow, oil, turpentine, &c., likewise give rise to the formation of unpleasant compounds when they are burnt at a low temperature. Every one must be acquainted with the odour of a smouldering candle or a badly-trimmed lamp; and when alcohol, ether, or wood-spirit are burnt at the temperature of glowing platinum, they produce a number of most irritating compounds, as aldehyde, acetic acid, formic acid, &c. This teaches us that combustion should at all times be kept up with as much energy as is compatible with the required effect, and that the product of its action should be disposed of as speedily as possible.

Effect of Cooling Influences on Flame.—Every circumstance that tends to lower the temperature of flame, operates to a like extent in diminishing the intensity of its light. We see this when a large "snuff" collects on the wick of a tallow-candle—the carbon of which radiates the heat so fast, that the temperature and light of the flame are considerably reduced; and by bringing a mass of metal in contact with a small flame, the latter is immediately extinguished. Sir Humphry Davy was the first to investigate facts of this description; and he showed, by his masterly researches, that flame cannot exist below a certain temperature. This is easily proved by intersecting the flame of a candle with a piece of wire gauze, having about thirty or forty meshes to the inch, by endeavouring to pass the flame through a ring of stout copper wire, or through a small hole punched in a sheet of that metal. In all these cases the flame will be extinguished above that point where the metal intersects it; and, although the inflammable vapour will continue to pass through the holes in the form of smoke, yet the cooling influence of the metal is so great, that the combustible gases will not be inflamed. The same process occurs when we place a layer of wire gauze over the glass or chimney of an ordinary gas-burner; the wire will, by its conducting power, so far reduce the temperature of the flame, that it will not pass through to the apertures of the burner. Sir Humphry Davy took advantage of this important fact, and applied it in the construction of the safety-lamp, which has been of such essential service to the miner. "The Davy," as it is termed, is nothing more than a common oil-lamp, with a cylinder or cage of wire gauze surrounding the flame (Fig. 84). This gauze permits the passage of light, but it will not allow the flame to traverse it; and hence it may be exposed to the most inflammable mixtures without danger of their explosion. The miner knows when the atmosphere of the mine is explosive, by the enlargement of the flame and the burning of the fire-damp within the cylinder of wire gauze, and he perceives a struggle, as it were, of the flame to pass out; but such a result is not possible, unless the cooling influence of the wire is prevented by its becoming almost red-hot. In this case there is danger; and the fire-damp of the mine may be exploded. These lamps are also employed in spirit warehouses, gas manufactories, in the sewers, and in many other localities where there is risk from explosion. The same principle was employed by Mr. Hemming in the manufacture of his safety jets for the oxy-hydrogen blowpipe. We have already said that the mixed gases which are used in this apparatus are exceedingly explosive; and if some contrivance were not adopted to prevent the backing of the flame, they would assuredly take fire. In fact, in the earlier experiments with the oxy-hydrogen blowpipe, this was a result of frequent occurrence; and Mr. Clarke tells us, in his work on the subject, that he often narrowly escaped being killed by the bursting of his apparatus. On one occasion, when he was experimenting in the presence of some friends, "the reservoir for the compression of the gases, although made of thick copper, was torn in pieces; and the fragments flew with the force of cannon-shot in all directions, like the bursting of a bomb." To guard against the danger of such terrible consequences, it was found necessary to protect the operator by means of a thick oaken screen. Mr. Hemming saw the disadvantage of this; and adopting the facts which Sir Humphry Davy had recently brought to light, he contrived a safety jet that enabled the operator to do away with all the paraphernalia that had hitherto protected his life. The jet consists of a tube of brass, about six inches long and three-quarters of an inch in diameter, packed full of fine copper or brass wire: the wire is cut into lengths of six inches, then packed as close as possible in the tube, and finally wedged together by means of a central bar of metal. In this way a number of fine apertures are left for the passage of the gas; and the conducting or cooling power of the wire is so great, that the flame cannot pass back to the reservoir of mixed gases.

---

* See *ante*, p. 32; article, "Heat."

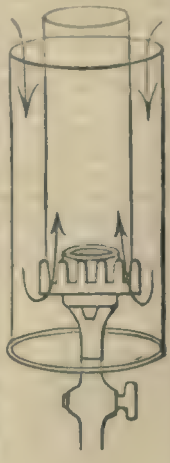
Fig. 84.



Another circumstance that operates in reducing the light and heat of flame is its rarefaction. When a flame is put under the exhausted receiver of an air-pump, it first enlarges, then the light diminishes, and finally it is extinguished. A flame of alcohol, ether, wood-spirit, wax, tallow, oil, or spermaceti, is extinguished when the rarefaction is carried to a fifth or sixth degree; hydrogen is extinguished when it is carried to a seventh or eighth degree; sulphur when it reaches the eighteenth degree; and phosphorus when it arrives at the thirtieth degree. "Slow combustion on the surface of platinum is exhibited by marsh-gas, down to a fourfold rarefaction of the air; by carbonic oxide, to sixfold; by vapour of alcohol, ether, or wax, to eightfold; by olefiant gas, to ten or elevenfold; by hydrogen gas, to thirteenfold; and by vapour of sulphur, down to a twentyfold rarefaction of the air."[*] From this it would follow, that the light emitted by any illuminating agent is not so great at the top of a mountain as at its base, or in the tropics as at the poles of the earth.

Lastly, it should be mentioned, that the supply of very cold air to a flame always diminishes its light by the abstraction of heat; and hence we may improve the illuminating power of any combustible substance by supplying it with atmospheric air that has been previously warmed. The Rev. Mr. Bowditch, of Wakefield, has contrived an apparatus whereby this may be effected in the case of common gas. He places a disc of metal or a cup of glass, having a hole in its centre, on to the screw which receives the burner. This disc, or cup, is made the means of supporting an outer glass, and thus of directing the air down over the surface of the hot chimney before it enters the flame from below (Fig. 85). It is stated that the light is increased about 25 per cent. by this arrangement.

Fig. 85.



PHOTOMETRY.

Intensity of Light and Heat.—We know that the power of light and heat diminishes as we recede from any object that produces it, and the decrease is in proportion to the square of the distance: for example, if we have a certain amount of light; at a foot from its source, the intensity will be one-fourth at two feet, because the square of two is four; one-ninth at three feet ($3\times3=9$), one-sixteenth at four feet ($4\times4=16$), one twenty-fifth at five feet ($5\times5=25$), and so on. Upon this law, as it is termed, is founded all the methods now employed for estimating the relative value of different illuminating agents. The practice is called *Photometry;* and there are various modes of conducting it. Count Rumford adopted the plan of adjusting the lights at such a distance from an upright rod, that the shadows produced by each on a white screen should be equal; he then measured the distance of each light from the rod, and, on squaring the number of inches, he obtained two sets of figures, which represented the relative values of the lights: by dividing the larger sum by the smaller, we obtain a product that expresses the fact in simpler terms. The late Mr. Ritchie contrived an apparatus that consisted of two pieces of glass, placed at right angles to each other, and so disposed, that the light from two opposite sources should be reflected upwards upon a piece of tissue-paper that covered two holes in a darkened chamber. When he had adjusted the instrument so as to obtain two reflections of equal intensity, he then measured the distances, and proceeded as before. Leslie and Wheatstone have also invented photometers, which are useful enough for certain purposes; but they have all given place to the very simple contrivance of Professor Bunsen. It will be noticed, that if a piece of white filtering-paper is painted over with melted wax or spermaceti, it acquires a greasy appearance, and becomes translucent: if this be done so as to leave a spot or disc, about the size of a shilling, untouched in the centre of the paper, we shall find that the apparatus will have the following properties:—When examined by reflected light—that is, with the light on the same side of the paper as the observer is—the disc will look white, and the surrounding greasy part dark; but by altering this condition of things, and looking at the paper by transmitted light—that is, with the light on the opposite side of the instrument—the disc will appear dark, and the surrounding greasy portion light and translucent. Lastly, if two lights of equal intensity are placed one on each side of the paper, the disc will disappear entirely; for then the light of one side neutralises that of the other, and there is no disposition to produce either effect. Upon this is founded the principle of Bunsen's photometer. The instrument consists of a graduated rod about five feet in length, having a support at each end. The prepared paper is held by a frame which slides upon the rod between the lights. This frame is usually enclosed in a darkened chamber, so as to exclude all light but that emanating from the object to be tested. The frame containing the paper is slid to one side or the other until the disc entirely disappears, and thus we read off the relative values of two lights. In making experiments on coal gas, it is usual to burn it at the rate of five cubic feet an hour, from an Argand burner having fifteen holes and a seven-inch chimney. The candle, which is used as a standard for comparison, is generally of sperm, and the rate of consumption is fixed at 120 grains per hour. When it happens that the consumption is greater than this, it may be reduced to the normal standard by a very simple calculation: thus—suppose that, on experiment, it was found that the light of the gas was equal to 11 candles of 140 grains' consumption; then, as 120 grains is to 140, so are 11 candles to the standard value—namely, 12·8 candles.

---

[*] Gmelin.

In this way the following results have been obtained; and, in order that an estimate might be made of the relative values of different illuminating agents in respect of their consumption and heating power, other results have been appended:—

	Consumption of each candle or burner per hour.	Number required to produce the same light.	Total consumption per hour.	Illuminating power in standard candles.	Heating power in lbs. of water raised 1°
Cannel coal gas . .	3·5 cub. ft.	2 burners	7 cub. ft.	28	4550
Common " . .	5 " "	" "	10 " "	"	6500
Sperm oil in Argand	450 grs.	5 lamps	2250 grs.	"	5448
Sperm candles, 6 to lb.	134 "	25 candles	3350 "	"	8223
Wax " " .	167 "	23 "	3841 "	"	8904
Cocoa-nut " .	143 "	26 "	3718 "	"	8664
British sperm " .	140 "	29 "	4060 "	"	8743
Composition " .	144 "	30 "	4320 "	"	8906
Oil in common lamp	133 "	36 lamps	4788 "	"	11505
Tallow moulds, 6 to lb	143 "	40 candles	5720 "	"	11793

The amount of heat, in these cases, has been determined by burning the lamp, or candle, under a vessel containing a given quantity of water, or in a space surrounded by a certain amount of that liquid, at a known temperature: from which it will be evident that, for the same amount of light, cannel gas produces the least heat; then follows sperm oil in an Argand or carcel-lamp; then common coal gas; then wax, sperm, and other candles; and, finally, oil in a common lamp, and tallow candles—both of which produce an enormous amount of heat in proportion to the light evolved.

CANDLES.

Materials employed in Candle-making.—It has been already remarked that candles are among the most ancient of illuminating agents, and it cannot be doubted that originally they were manufactured in a very rude way, by simply smearing a porous combustible solid with animal fat; but, at the present time, a number of fatty substances are employed in their manufacture, and great pains taken to have them as pure as possible. We have, for example, tallow and its derivatives stearine and stearic acid, margarine and margaric acid; palm oil and its constituents, palmitin and palmitic acid; cocoa-nut oil, cocinin and cocinic acid; spermaceti, wax, paraffin, &c. All these require to be purified before they can be converted into candles; and hence the necessity for describing them in detail.

The *wicks of candles* are of three kinds; namely, the pith of a rush (*Juncus effusus*), which grows abundantly in marshy places; and of cotton, which is either rolled into skeins or plaited into strands. The first is used for the common rushlight, the second for ordinary dips and for wax-lights, and the third for spermaceti, stearic acid, stearine, and other candles which do not require snuffing. In many cases it is necessary to prepare the wicks with a salt of ammonia, as the phosphate, borate, or sulphate, in order to keep them from clogging, and to give them a sufficient degree of rigidity to enable them to stand firmly up when they are burning. This was an improvement introduced in 1836, by M. De Milly, of Paris. Dr. Ure says that the best wicks are still imported from Turkey, and they are composed of skeins of unbleached cotton. The wick of wax mortars and night-lights are made of flax, as cotton is not able to resist the long-continued action of the high temperature of the flame.

Varieties of Candles, and their Manufacture.—Two sorts of candles are commonly met with in commerce—namely, *dips* and *moulds*. The former are made by repeatedly dipping the wicks into melted fat, allowing a sufficient time between each of the dippings for the tallow or fat to cool. Usually the wicks are cut into proper lengths by a machine, according to the sort of candle to be made, and then suspended from a rod or frame, called a port; by this means the workman is enabled to dip a number of candles at the same time. In large establishments the ports or frames are attached to a revolving beam, so that, without much exertion, the workman can successively dip one port after another, and thus make from seven to eight thousand candles in a day. The tallow is kept in the dipping-vessel, at a temperature just over the point of solidification.

Mould candles are made in a tubular mould, which is either of pewter or glass. The mould consists of two parts—namely, the cylinder and the cap. The former is of the full length of the candle, and is highly polished in the interior, so as to allow the candle to slip easily out of it. The latter is a small cup, having a hole in the centre for the passage of the wick; it is fixed on to the bottom of the cylinder, and serves to give the taper-form to the top of the candle. Sometimes there is a third piece, called the foot, which is a sort of funnel, that is screwed on to the opposite end of the cylinder, and serves for the guidance of the melted fat into the mould. Eight or ten of these cylinders are usually fitted into one frame, which has the upper part formed into a trough for the reception of the melted tallow. The wicks are drawn into the cylinders by a hooked wire, and kept in their places by a wedge, which fixes them in the cap of the mould; the other end being held by a rod which passes across the frame. When all is ready, the liquid fat is run into the trough, and thence into the moulds, until each cylinder is full. After it has thoroughly cooled, the surplus fat is scraped out of the trough, and, the wedges being removed from the hole in the cap, each candle is drawn out of its mould by means of a hooked wire, which catches hold of the loose end of the wick. The candles are then cut of one uniform length, and trimmed up for the market.

The cheaper sort of mould candles are those manufactured by Price and Company, and are made by machinery, eighteen candles being moulded at one time. The wicks are made in lengths of sixty yards; eighteen of these wicks are wound off upon eighteen separate rollers, and a roller is placed over each mould. The wicks having been passed through the cylinder, are seized at the lower end by a set of eighteen forceps, which draws them tight, and fixes them in their places. The moulds, which during the operation have remained in a horizontal position, are now turned in a vertical direction, the small end downwards, and are passed upon a railway to the person who fills them. In their course they have traversed a hot closet, and have thus acquired a proper temperature for receiving the tallow. When full, they are pushed on to other railways, and allowed to cool. This being accomplished, they are brought back in succession, by means of turn-tables, to their former places. The frame is then placed in a horizontal position; and eighteen plungers or pistons press forward the loose caps of the moulds, and thus push out the candles, and deliver the wicks for another operation.

Wax and Paraffine candles are usually moulded by hand, in consequence of their sticking so tight to the sides of the mould, that they cannot be drawn out of it. The operation for wax candles is conducted as follows:—The wicks are first warmed in a stove, and then suspended to a hoop over the vessel of melted wax. The latter is then poured from a ladle over each wick in succession; and to prevent the wax from accumulating more on one side of the wick than the other, the wick is sharply rotated between the finger and thumb. When the candles are thus coated to about one-third their proper size, they are allowed to cool for a short time, and the operation is then repeated until they are half-made. This being accomplished, they are removed from the hoop, and rolled between two marble slabs until they are of one uniform thickness. The upper end of each candle is now formed by cutting it down to a metal tag, which covers one end of the wick. The candles are then again suspended to the hoops, but in a reversed position; and the operations of basting and rolling are repeated as often as necessary. Finally, the lower ends of the candles are cut square, so as to make them of the desired length.

The large wax candles used in churches are formed by rolling the wick in a thin layer of wax, and then, after adding layer after layer, it is finished off in the way just described.

Long wax tapers are made by winding the wick on a drum, and then leading it, by means of a guide-roller, into a trough of melted wax, from which it passes through a series of holes progressively smaller and smaller, on to a second drum, where it is wound up—the operation being somewhat like that of wire-drawing. A little turpentine is added to the wax to render it pliable, so that it may not crack as it bends over the drum.

We proceed now to speak of the different kinds of fats, and of the candles made from them.

Tallow is obtained from animals; it is the fat which is located under the skin, about the intestines, in the bones and muscles, and around the kidneys. It is extracted by cutting the tissue into small pieces, then submitting it to heat, and finally to pressure. The tallow or fat of bones and the dressings of skins is obtained by boiling them in a large caldron, and skimming off the fat as it rises to the surface. A large quantity of tallow is obtained from meat during the ordinary operations of cooking; and this is known in commerce by the name of kitchen-stuff. Tallow, when first obtained, has a very disagreeable smell; indeed, it contains a great number of impurities, as blood, animal tissue, water, &c.; and in this condition it is not suited for the manufacture of candles. To render it pure, it is submitted to various operations, which are called *rendering*. One of these is as follows:—The tallow is melted in a large copper set upon an open fire, and the water contained in the impure fat is boiled away; during this stage of the operation the animal tissues and bloody matters coagulate and rise to the surface. These are strained off and pressed, the residue is sold under the name of greaves or cracklings, and is used for feeding dogs. Another mode of rendering, is to submit the melted tallow to the action of steam, which is blown into it from a pipe pierced with a number of holes. But the most effective process of all is that recommended by M. D'Arcet: the tallow is melted by steam-heat, and then treated with very dilute sulphuric acid; this destroys the colouring matter, and separates the animal tissue in the form of black flakes, which speedily settle to the bottom of the vessel. After drawing off the tallow, and washing it well with warm water, it is allowed to stand until it rises to the surface and is cold. In this state it is nearly free from colour and smell. Some years ago Mr. Watt obtained a patent for purifying tallow by a mixture of acids, as sulphuric, oxalic, nitric, and chromic; the two latter of which give out oxygen gas, and thus bleach the fat.

Tallow consists of several fats; one of which (oleine) is liquid at ordinary temperatures; and the others (margarine and stearine) are solid. Occasionally, also, when it has been obtained from particular animals, it contains a few other fats, as hircine, butyrine, &c. The relative proportions of these fats give to tallow its different consistence; for example, beef-marrow, or bone-fat, which is rather hard, contains 76 of stearine to 24 of oleine; mutton fat, 62 to 38; beef fat, 54 to 46; butter, 40 to 60; hog's-lard, 38 to 62; goose fat, 32 to 68; and turkey fat, 26 to 14. Again, the melting-point of different tallows varies with the proportions of these constituents; for, while common tallow melts at from 94° to 104° Fah., marrow fat requires a temperature of 115° to liquefy it, and hog's-lard is fluid at 81°.

Three sorts of candles are made out of ordinary tallow; namely, rushlights, dips, and moulds. The former are not much employed in towns, except for watch-lights; but they are still the favourite candle with the poor in country villages; and it is very probable that they are chosen because of their not guttering so much as the common dip when they are exposed to currents of air: besides which, they burn longer, and are, therefore, more economical. In many cases these candles are made by the peasants themselves. Mr. Gilbert White has given an account, in his *Natural History of Selbourne*, of the manner in which they are produced by the cottagers of Hampshire. They take a quantity of rushes, which have been previously peeled, and dip them into the melted tallow, so that six pounds of tallow shall serve for 1,600 rushes. In this way they produce candles which require 228 to make a pound. The rushes are peeled on three sides for the best lights, and on two only for watch-lights, and which, says Mr. Gilbert White, only shed a dismal light—darkness visible. Of the other kind, a good one, which measured 2 feet 4½ inches in length, burned 57 minutes; and he was assured by an experienced old housekeeper, that 1½lb. of rushes, after having been coated with tallow, completely supplied her family for a year. The cost of lighting with rushes he estimated at one farthing for 5½ hours; whilst a halfpenny candle, in the blowing, open rooms of the poorer classes, only lasted two hours. The rushlights that are sold in London vary from ten to eighteen in the pound. A specimen of ten to the pound, which measured 11½ inches in length, burnt at the rate of 1½ inches in the hour, equal to a consumption of 74 grains; and it took five of them to give the light of one sperm of 120 grains per hour.

Ordinary dips burn with great irregularity—even the same candle will vary from 120 to 180 grains per hour; and, when consumed at the standard rate, they give a light which is just one-third that of sperm. Dips are made of all sizes, from six to sixteen in the pound; and they are sold at from 5*d.*, and upwards, per pound, according to the price of tallow.

Mould candles, of tallow, are generally made of the better description of fat; they are, therefore, whiter than dips, and melt at a little higher temperature. A mould candle, of six to the pound, burns at the rate of about 143 grains per hour, and its illuminating power is rather more than half that of a sperm of 120 grains; so that, weight for weight, its power is about half that of sperm.

The disadvantages attending the use of tallow candles are, that they melt at a very low temperature, and are, therefore, not suited for warm climates or hot rooms; they gutter when they are exposed to draughts; they require constant snuffing; they give out an unpleasant smell, both before burning and after; they soil the hands, and grease everything with which they come into contact; and, in warm weather, they are very apt to break. Some of these disadvantages have been overcome by the chandlers of Dublin, many of whom have acquired a high reputation for the superior quality of their mould candles; and it has been found, that by waxing the wicks before they are used for making the candles, the disposition to gutter, which is so objectionable, is in a great degree prevented. Candles of this description generally fetch from a halfpenny to three-farthings a pound more than the commoner sort.

Palm oil is the produce of the *Elais Guiniensis*, or *Avoira elais*, a palm that grows very abundantly in the tropical parts of Africa. Most of the palm oil that we receive into this country comes from the western coasts of that continent—chiefly from Guinea. It is obtained by crushing the fruit, then submitting it to the heat of boiling water, and, finally, to pressure. The oil has a buttery consistence, is of an orange-yellow colour, has a sweetish taste, and an agreeable odour. When new, it melts at a temperature of 81° Fah.; but, if old, it requires a heat of from 90° to 96° to liquefy it. It consists of about 69 of oleine, and 31 of a solid fat named palmitine. The crude oil is readily bleached by exposing it to light and air, or to chlorine gas, and it may also be purified in the same way as common tallow. Until it is deprived of its great excess of oleine, it is not fit for the manufacture of candles.

Galam or Ghea butter is another fat oil, that closely resembles palm oil: indeed, it is very often mistaken for it. It comes from the western parts of Africa, and is the produce of a palm, the *Micadenia*, or *Bassia Parkii*—a tree that is very similar in its appearance to the *Bassia latifolia*, and the other species of *Bassia* that are indigenous to the province of Hindostan. According to Park, the tree is very abundant in Bambara; and the oil is obtained from the fruit in the same way as palm oil. Ghea is of a greyish-white colour; it melts at a temperature of 97° Fah., and consists of about 68 of oleine, and 32 of a solid fat like palmitine.

Cocoa-nut oil or fat is extracted from the kernel of the common cocoa-nut, which is the fruit of a palm named *Cocos nucifera*. The oil is semi-fluid, or rather buttery, in its consistence. It melts at a temperature of 68°, and contains two or more fatty principles, one of which, namely, the oleine, amounts to about 71 per cent., and the other, cocine or cocinine, to 29. The oil is not fit for the manufacture of candles until it has been submitted to cold and pressure. We import this oil from several parts of India, from the islands of the Pacific, from Australia, and from Borneo.

Several kinds of vegetable fats or butters, well suited for the manufacture of candles, have at various times been sent to this country; but the demand for them has not been sufficiently great to encourage a trade. Among these may be mentioned the solid fats obtained from three species of *Bassia*, indigenous to India. These are, *Ilpa oil*, or *Eloopei unnay*, which is expressed from the seeds of the Illupie tree, or *Bassia longifolia*—a tree that is very abundant in the Madras Presidency, and in the southern parts of Hindostan. This oil is white, and it requires a temperature of from 70° to 80° to melt it. Similar fats are obtained from the seeds of *Bassia latifolia*, of the Bengal Presidency, and *Bassia butyracea*, of the province of Dotee—the former is named *Epie*, or *Mahowa seed oil*, and the latter *Phoolwa*, or *vegetable butter*. A solid oil, of a pale greenish colour, is obtained from the tallow-tree of Java—probably a species of *Bassia*, which is common not only to Java, but also to the western countries of the Archipelago. In fact, it appears, from the observations of Mr. Lowe, that several kinds of solid oil are obtained in the islands of the Archipelago from different species of *Dipterocarpus*. These oils are hard, yellowish-green, and brittle, and they melt at about 90° Fah. An oil named *Piney tallow* is expressed from the fruit of the panoe tree (*Vateria indica*), which grows abundantly in Malabar and Canara. The oil is white, solid, and fusible at 97°; it makes excellent candles, which do not give out any unpleasant smell in burning. *Cocum oil*, or *Kokum butter*, is obtained from the seeds of a kind of mangosteen (*Garcinia purpurea*), which is common in several parts of the peninsula. It is of a pale greenish-yellow colour, and it melts at 95°. *Kali-ziri*, or *Khatzum butter*, another variety of fat oil, is in all probability the produce of the seeds of *Vernonia anthelmintica*, or of *Salvadora Persica*, both of which are common in Guzerat and Concan Ghats; it is a bright green oil, of the same fusibility as the last-named. The seeds of *Carapa Guianensis*, of Guiana and Acagie, yield a semi-solid oil, named *Crab* or *Carapa oil*; and, lastly a solid fat called *Neem oil*, or *Vaypum unnay*, is obtained from the ripe fruit of the margosa tree (*Melia azadirachta*). All these fats might, if necessary, be largely supplied to this country, and thus be the means of keeping in check the high price of tallow, or even of taking its place altogether.

Stearine, Margarine, Palmitine, Cocine, or Cocinine, &c., are the names applied to the solid fats contained in tallow, suet, lard, palm oil, ghea butter, cocoa-nut oil, &c. It has been already stated, that none of the raw fats, except tallow, can be applied at once to the manufacture of candles; but they must be subjected to certain processes in order to remove the oleine or liquid constituent, and so obtain the fats in a more solid state.

As far back as the year 1799, Mr. William Bolt took out a patent in this country for the manufacture of candles from compressed tallow. This, perhaps, was the first attempt ever made to improve the quality of candles by fabricating them from the solid constituents of fats and oils. About twenty years after this, the researches of Chévreul gave an impetus to the discovery of Bolt, by showing that all the fats consisted of at least two proximate elements—namely, an oily or liquid portion, which he named oleine, and one or more solid constituents, which he called stearine, margarine, &c. Taking advantage of this fact, the candle-makers soon adopted a process whereby they were enabled to separate the one fat from the other, and thus to procure a material which would not melt at so low a temperature as ordinary tallow. To effect this, the tallow, palm oil, or cocoa-nut oil is melted, and then allowed to cool as slowly as possible, care being taken that it is constantly agitated during the whole time that it is solidifying. When the mass has acquired a pasty consistence, it is transferred to horsehair or linen bags, and submitted to great pressure. In this manner the oleine is squeezed out, and the solid fats are left in nearly a pure state By repeating the process of liquefaction and pressure, the stearine, margarine, palmitine, and cocinine are obtained still purer. In this condition they are perfectly white, hard, and nearly free from greasiness, and they melt at a much higher temperature than the original fats: for example, common tallow melts at from 99° to 104° of Fah.; whereas stearine, which is obtained from it, melts at 144°, and margarine at 117°. Palm oil is fluid at from 90° to 96°; but palmitine requires a heat of 124° to melt it; and lastly, cocoa-nut oil is liquid at 68°, while its solid constituent, cocine or cocinine, is fusible at 110°. These fats are employed in the manufacture of *composition* and *Palmer's candles*. The former burn at the rate of from 140 to 155 grains per hour, and they furnish a light which is scarcely inferior to sperm; the latter have an average consumption of about 160 grains per hour for each wick, and the light emitted is in the same ratio as the former.

Stearic, Margaric, Palmitic, Cocinic, and other solid Fatty Acids, are obtained from the oils, &c., already named; indeed, the solid fats which have just been described contain in each case a still more solid compound, which bears the name of the fat from which it is derived. These acids were discovered by Chévreul in the year 1823; and, two years afterwards, he thought them of so much importance, that he allied himself with Gay Lussac, and took out patents in this country and in France for their manufacture. But, notwithstanding that they furnished candles of the very best description, and have since been made the basis of most profitable speculation, they did not realise any advantage whatever to the original patentees; in fact, the processes of Chévreul and Gay Lussac were so complicated and expensive, that they could not be followed out with profit or advantage: in addition to which, it was found that the candles manufactured from the fatty acids would not burn with an ordinary wick; and hence the necessity for still further improvement in this direction. Cambacérès, however, overcame this difficulty by inventing the present description of plaited wick; and this was afterwards improved by De Milly, who suggested the use of boracic acid and the salts of ammonia for impregnating the fibres of the cotton. Another obstacle to the use of the fatty acids was the pertinacity with which they crystallised; thus rendering the candles brittle, unsightly, and irregular of combustion. An attempt was made to remedy this by introducing fine powders into the melted acids, so as to break their grain; but then it was necessary to use powders of a volatile nature which would not clog the wick, and in an unfortunate moment they made choice of white arsenic. The introduction of this deadly poison into candles soon created alarm, for they produced very injurious effects on those who inhaled the vapours of combustion; and, in fact, it brought the discoveries of Chévreul into so great disrepute, that it almost annihilated the infant art of stearine candle-making. "It is true," say the jurors in their report on the candles of the Great Exhibition, "this deleterious substance was added in very minute quantities, yet it was entirely incompatible with health, and was soon prohibited on the continent by authority, and in England by equally powerful public opinion." Here commenced all the manufacturer's troubles anew. In all directions he sought a substitute, and yet found none: at last, after innumerable experiments, and when almost driven to despair, he hit on two simple expedients that answered the purpose in the most admirable manner. They were the addition of a very minute quantity of wax to the melted fatty acids, or allowing the acids to cool almost to the point of congelation before they were poured into the moulds. By this means a sort of liquid pulp is obtained, which sets in the moulds without crystallising. This is the plan adopted at the present time; the melted acids being constantly stirred during their congelation, and the moulds warmed to a temperature of about 110° Fah. before the semi-fluid mass is poured into them.

Two, if not three, distinct processes are employed at the present time, for the preparation of the fatty acids. *The saponification process* is founded on the discoveries made by Chévreul in the year 1823; namely, that when fatty matters are boiled with potash, soda, or lime, they are converted into soap by the union of the fatty acids with the alkali; and that from this soap the acids may be obtained in a more solid condition by the action of a stronger acid, as the sulphuric or hydrochloric. Chévreul saw the importance of his discovery, and took out a patent for the manufacture of the acids from soaps made with potash or soda. These, however, were found to be far too expensive; and in the year 1831, De Milly directed attention to the use of lime.

The following is an outline of the process as it is conducted at the works of the Apollo Company at Vienna; and of De Milly in Paris, Brussels, and Vienna. The process is divided into three stages: namely, the saponification of the fat; the decomposition of the soap by a strong acid; and the removal of the liquid oil and other impurities by means of pressure.

(*a.*) *The saponification of the fat* is effected by melting the tallow, or the palm oil, in a large vat, by means of steam which issues from a pipe perforated with holes, and then stirring in a quantity of lime in the state of thin cream; ten or fifteen parts of dry lime being used for every 100 of fat. The mixture is kept in a state of ebullition for five or six hours, or until it is completely saponified. It is then allowed to stand, in order that the impurities may settle to the bottom, and the melted soap rise to the surface and cool. The soap thus formed is very hard, and is generally called rock. It is ground to a coarse powder, and is then ready for the next operation—

(*b.*) *The decomposition of the soap by a strong acid.* The ground rock-soap is placed in wooden vats lined with lead, and, after being drenched with water, it is raised to a boiling temperature—the heat being applied in the same way as before. At this moment the soap is treated with dilute sulphuric acid, using about twenty-five of the strongest acid to every 100 of tallow or palm oil. In this way the soap is decomposed; its lime unites to the acid of the vitriol to form sulphate of lime, or plaster of Paris, which partly dissolves in the water, and settles to the bottom of the vat, while the fatty acids are set free and float to the surface. These are called "yellow matter;" and, after having been well washed with warm water, they are poured off into vessels called "jacks," and from thence into shallow tin pans, where they cool.

(*c.*) The cakes thus obtained consist of the solid and liquid acids of the fat; to separate which they are placed in horsehair bags, and subjected to hydraulic pressure, gradually increased up to about six hundred tons. This is extended over a period of six or eight hours, during which the liquid oleic acid runs out, and carries with it the brown colouring matter of the fat, leaving the solid fatty acids in a nearly pure condition. It is generally thought necessary to re-melt the acids, and to treat them with a little dilute sulphuric acid, so as to remove iron and other impurities that may have been acquired in the act of pressing. After this they are again cast in shallow pans, then placed in bags, and submitted to a more moderate pressure of about forty tons. During the last operation the cakes are slightly warmed in an atmosphere of steam, so as to facilitate the removal of the last portion of oil. In this way a solid mass is obtained which has all the appearance of ivory; and the product amounts to about thirty per cent. of the fat originally used.

The second or vitriolic acid process for obtaining the fatty acids, was originated in 1836, by M. Frémy, who discovered that these acids have the power of combining with concentrated sulphuric acid, to produce compounds which are named sulpho-stearic, sulpho-oleic, sulpho-margaric, sulpho-palmitic, and sulpho-cocinic acids. These are readily decomposed when they are brought into contact with boiling water, the sulphuric acid being dissolved by the latter, while the fatty acids are set free and float to the surface. This fact was made the basis of two patents, which appeared in the year 1840. One of these was taken out by Mr. George Gwynne, who proposed that the fats should be separated from the acids by distillation; and the other was obtained by Mr. George Clark, who advised that the acids should be set free by simply washing the product. But neither of these patents produced successful results; and it was not until the year 1844 that the process was so perfected by the labours of Jones, Wilson, and Gwynne, as to be applicable to the purposes intended. In that year the names of Wilson and Gwynne are found associated in a patent which still continues to be in force. The process adopted by those patentees is now extensively practised at the works of Price's Candle Company, at Vauxhall and Battersea; and at those of MM. Masse and Tribonillet, at Paris; of Motard, at Berlin; of Bert, at Gijon, in Spain; and at one of the works of the Milly Company at Vienna.

The fats usually employed for this purpose are, palm oil, refuse grease from glue-making and bone-boiling and ordinary tallow. The process is as follows:—

1st. *The Decomposition of the Fat with Sulphuric Acid.*—This is accomplished by first melting the oil or fat in a leaden vessel by the aid of steam, then allowing it to stand for a short time, in order that the mechanical impurities may subside. The liquid fat is now pumped into another vessel, and heated to a temperature of 350° Fah. While in this state it is subjected to the action of strong sulphuric acid—using about 6 lbs. of acid to 112 lbs. of palm oil. The acid quickly decomposes the oil, and gives it a black colour. The latter is now drawn off and transferred to a washing-tank, where it is boiled up with water by means of a jet of steam. After two or three washings it is ready for the next operation.

2nd. *The Distillation of the Fatty Acids by means of superheated Steam.*—The dark liquid fat of the washing-tank is conveyed into a copper still, where it is heated to a temperature of 560°, and submitted to the action of steam that has been heated to a very high degree by passing through a system of pipes set in a furnace. The hot steam raises the fatty acids into vapour, and carries them over into a series of vertical pipes, which act as condensers. These are kept at a temperature of 212°; and consequently they retain the fatty acids, but do not arrest the steam. Towards the end of the process it is necessary to elevate the temperature of the furnace in which the still is set, and also to raise the heat of the steam, in order that the whole of the fatty matter may be distilled over. The residue in the still, after this operation, looks like pitch, and may be employed for the same purposes.

3rd. *The cold and hot pressing of the Fatty Acids.*—These are effected in the same way as that described in the saponification process.

The other process to which we have referred—namely, that portion at the works of Jailon, Monier and Co., at La Villette, near Paris—is a modification of De Milly's lime process. It consists in passing a rapid current of sulphurous acid into the lime vat while the rock mass is forming; and thus of increasing the amount of solid fat by the conversion of the liquid oleic acid into solid elaidic. In this way the very commonest tallow may be used, for the sulphurous acid acts as a bleaching and deodorising agent. The subsequent stages of the process are the same as De Milly's.

Lastly, it may be said that a large quantity of the fatty acids which enter into the composition of ordinary soap, is obtained at the grease-works of Mr. Banwens, at Wakefield, from the waste lyes and suds of the woollen, silk, and cotton manufactories. It is calculated that about 11,000 tons of fat and oil are annually expended in this country in the cleansing and preparing of the fabrics in question. Hitherto all this had been allowed to run to waste; but the energies of Mr. Banwens having been directed to the subject, it is hoped that the larger portion of the fatty acids contained in the soap and oil will be retrieved. These acids are worth about £15 a ton; and if only half of them are annually recoverable, as much as £93,500 will be annually secured. The acids are obtained by treating the boiling suds with a little oil of vitriol or spirits of salt: the liquefied fats rise to the surface, and, when cold, may be skimmed off, or otherwise collected. The fats are then cast into blocks, and pressed in the usual manner.

In whatever way the solid fatty acids are obtained, they always present the following characters:—They have the appearance of ivory, or of fine spermaceti: they are inodorous, and do not communicate a greasy stain to paper, or soil the fingers: they melt at a much higher temperature than the original fats: indeed, the melting-point of pure stearic acid is 167°; that of bassic acid, which comes from the palm fats of India, is 159°; that of palmitic and margaric acids, 140°; and that of cocinic acid, from cocoa-nut oil, is 110°. It rarely happens, however, that these acids are obtained perfectly free from a small proportion of liquid oleic acid; and hence the melting-points of the acids, as found in commerce, are a little below the preceding. Stearic candles generally melt at from 130° to 132° Fah.

These candles, of six to the pound, burn at the rate of from 140 to 144 grains per hour, and they give a light, as nearly as possible, the same as sperm. If there be any difference, the light of sperm is a little greater, and that of stearic acid a little whiter. When calculated into an average consumption of 120 grains per hour, it will be found that, for equal weights consumed, 15 sperm candles will give the light of 16·5 stearic. The advantages which are attendant on the use of these candles are, the great regularity of their burning, the dryness of the cup below the flame, the absence of all disposition to gutter, of not softening in warm climates or hot rooms, and of not soiling the fingers or clothes. It is very probable that stearic candles will, ere long, supersede every other description of *bougie*.

The candles which are manufactured by Price and Co., from the fatty acids obtained by the distillation of *Chinese vegetable tallow*—the product of *Stillingia sebifera*—are even more infusible than the last; for they require a temperature of 136° to liquefy them. A patent has been taken out by Messrs. Wilson, Gwynne, and Wilson, for the manufacture of candles from this material.

Spermaceti.—This remarkable fat is chiefly obtained from the great spermaceti whale, or great-headed cachalot (*Physeter macrocephalus*), which inhabits the Pacific Ocean, the Indian Ocean, and the China Sea. It is also obtained from other species of cachalot, as the *Physeter cetadon*, *trumpo*, *cylindricus*, *microps*, &c.; and from the two kinds of dolphin, viz., the *Delphinus turno* and *edentulus*. The spermaceti is found in all parts of the bodies of these animals, mixed with the common fat or blubber; but the great receptacle for it, in the *Physeter macrocephalus*, is a large excavation or case, situated in the upper jaw, directly in front of the skull, and above the nostrils. This receptacle is opened by the whalers directly the animal is captured; and the liquid contents, consisting of oil, spermaceti, and cellular matter, are dipped out. The dense mass of cellular tissue, called junk, which lies immediately beneath the case, is also removed; and when boiled, it furnishes an inferior kind of oil and spermaceti. The contents of the case are carefully boiled, and then strained off into casks. In this state it goes by the name of "head-matter;" and is composed of spermaceti and sperm oil. After standing for some time at a temperature of from 40° to 50° Fah., the spermaceti solidifies as a dirty-brown crystalline mass. This is separated from the oil by straining through bags, and pressing. The crude spermaceti is melted by the aid of steam, and then allowed to cool very slowly; after which it is ground to powder, placed in bags, and subjected to enormous pressure—a pressure of six hundred tons. In this way the residue of the oil is squeezed out of it, and the spermaceti which remains is nearly white. To purify it still more, it is melted in a large iron vessel, and boiled for some time with a solution of caustic soda. This has the effect of converting all the oil with which it is contaminated into a soap, which dissolves in the water, while the spermaceti floats to the surface. It is now run into tin pans and allowed to cool. The mass so obtained is crushed to a powder a second time, and then pressed as before; the operation being conducted in an atmosphere heated by steam. Finally, the spermaceti is boiled with a strong solution of potash; and when it is perfectly limpid and colourless like water, it is cast into square blocks.

In this condition it is named *cetine:* it is a white crystalline solid, with a pearly lustre and greasy feel. It melts at a temperature of 120°; and it consists of a fatty acid (*cetylic*), which fuses at 131°, and a species of alcohol, named *ethal*, which melts at 118°. Impure kinds of spermaceti liquefy at from 112° to 160°.

Spermaceti candles contain about three per cent. of wax, which is added to break the grain, or to prevent crystallisation. A sperm candle of six to the pound burns with great regularity if it be properly made; but those in commerce at the present time, are but poor examples of what such candles should be, for they range in combustion between 120 and 146 grains per hour. A spermaceti candle of six to the pound, burning at the rate of 120 grains per hour, is generally taken as the standard of comparison for all other illuminating agents, for the light emitted is clear, white, and very brilliant. The candles which are sold under the name of *transparent wax*, are mostly sperm candles, coloured with a little gamboge.

Wax is obtained from several sources: it is secreted between the abdominal scales of the honey-bee, and formed by that insect into honey-comb. The insect wax of China is produced by the male of the *Coccus ceriferus*, which deposits it on the trees on which it feeds, especially the *Rhus succedaneum*. A soft, tenacious, mahogany-coloured wax is obtained in great quantity at the Brazils, and is the product of a black bee which hives under ground. Vegetable wax is procured from the berries of several myrtles (the *Myrica cerifera*, *augustifolia*, *latifolia*, &c.), which grow abundantly at the Cape of Good Hope, and in South America: besides which, there are many trees, in Japan and St. Domingo, which yield substances resembling wax; these are the *Croton sebiferum*, *Celastrus ceriferus*, and *Ceroxylon audicola*. A wax-like substance, named *cerosine* by Dumas, is also obtained from the surface of many species of sugar-cane; and Mulder informs us, that the skins of apples, and the berries of the mountain-ash, yield abundance of wax: in fact, wax is a very common product of the vegetable kingdom: it forms the bloom of fruits and of young leaves, and it is a large constituent of the green and yellow colouring matter of plants (*Chlorophylle* and *Xanthophylle*).

The wax of English commerce is procured from the honey-comb; the comb being first allowed to drain in order to remove the honey, after which it is boiled up with water, and permitted to stand until cold, when the wax solidifies upon the surface as a brownish-yellow cake. This is purified and bleached by the following processes:—The wax is cut by machinery into very small shavings, and put into a vat with water, and a little concentrated sulphuric acid—the proportion of acid being a pint to a ton. Steam is then blown into the vat by means of a coiled pipe pierced with holes; and the mixture is kept in constant agitation. After a time it is allowed to stand quiet, when the impurities subside to the bottom, and the wax floats to the surface as a clear and almost colourless liquid. It is now run into a trough named a cradle, which has a number of holes about the size of a quill in the bottom of it. This trough is placed over a drum or wooden cylinder, which revolves in a tank of water: the melted wax, running in small streams upon the revolving wet drum, is floated off upon the surface of the water in the form of exceedingly thin strips or flakes, called ribbons. These are collected at the opposite end of the tank; and, after being drained in baskets, they are spread out upon tables, and exposed to the air and light to bleach. This occupies a period of from five to ten weeks, during which the flakes are frequently wetted and turned. They are also melted and ribboned once or twice during the process, in order that fresh surfaces may be exposed, and the whole acted on in a uniform manner. When the wax is sufficiently white it is melted in vats, and cast into thin cakes.

Different kinds of wax bleach with different degrees of facility: thus the wax of England, Hamburg, Odessa, Portugal, Mogador, Zanzibar, the East and West Indies, and North America, bleach very rapidly; while those of Cuba, Dantzic, Königsberg, Gabon, and Gambia, bleach with difficulty; and the soft mahogany-coloured wax of the Brazils cannot be bleached at all.

Pure wax is solid up to the temperature of 148°, but unbleached wax melts at from 144° to 146°. It contains about twenty-two per cent. of a peculiar fatty acid (*cerotic*) which was formerly named *cerine;* and the remainder consists of a compound substance named *myricine*, which Mr. Brodie says is composed of the solid acid of palm oil (*palmitic*), and a species of alcohol, which he has named *oxide of melissyl*. Chinese wax is entirely free from myricine, and is made up of cerotic acid and an alcohol named *oxide of cerotyl*. Cerine and myricine are distinguished from each other by the following properties:—Cerine is soluble in boiling alcohol, from which it is deposited as the spirit cools; but myricine is wholly insoluble in that menstruum. Cerine melts at from 162° to 172°, while myricine fuses at as low a temperature as 147°.

Wax candles are rarely composed of pure wax, but consist of wax and stearine, or stearic acid, in various proportions. The candles of commerce are very irregular in combustion; in fact, they burn from 135 to 175 grains of wax per hour; and they give a light which varies from one up to three, according to the condition of the wick. At the best of times the light of wax is, weight for weight consumed, about one-sixth less than that of spermaceti.

We do not employ much wax in this country for candle-making, as preference is now given to sperm and stearic candles; but, on the continent, it is still made use of to a great extent in the fabrication of candles for religious purposes, and also for holiday and *fête* occasions. In the Greek church, wax and oil are the only illuminating agents allowed; and, in the Romish church, large wax tapers are also employed during divine service. These, as well as the candles for weddings, *fêtes*, and saint-days, are generally ornamented either with spirals of gold, or with different devices in colours—the colours being artificial ultramarine for blue; a mixture of verdigris and emerald green, or verdigris alone, for green; chromate of lead, or gamboge, for yellow; vermillion for red; and madder lake, or alkanet root, for pink. The best description of candle manufactured from wax is the *mortar-light*, which is used either for night watching or for heating dishes on the table. On the continent these lights are termed *veilleuses*.

Paraffine.—About twelve years ago, the sagacity of Liebig led him to remark, that "it would certainly be esteemed one of the greatest discoveries of the age, if any one could succeed in condensing coal gas into a white, dry, solid, odourless substance, portable, and capable of being placed upon a candlestick or burned in a lamp."[*]—In the course of the last few years this grand result has been effected; indeed, we may say that the germ of the discovery was brought to light more than twenty years ago, by the researches of Reichenbach and Christison. The former of these chemists showed that the thick heavy oil procured by the distillation of tar from beech-wood, contained a solid crystalline body, which he named *paraffine;* and the latter, in examining Rangoon petroleum, discovered a substance which he called *petroline*. Both of these compounds are identical in their chemical composition with the illuminating principles of coal gas, and they are now known to be one and the same thing. The term paraffine is still employed to designate the substance, in consequence of its weak affinities (from *parum*, little, and *affinis*, affinity). Since that time, it has been procured by Mr. Rees Reece and Sir Robert Kane, from peat; by M. Ettling and Mr. Brodie, from wax; by Mr. Young, from Boghead coal; and by others, from the bituminous schists of England, France and Germany. In all cases it is obtained by destructive distillation; and the following are the processes which are commonly employed.

The plan proposed by Reichenbach was to distil wood-tar to dryness, and to separate the heavy oil which is thus obtained, from the water and light oil that also come over during the process. This is distilled a second time, and only the last portions are retained. These are treated with concentrated sulphuric acid, then with water, and finally with boiling alcohol, from which the paraffine separates in the form of crystalline plates as the spirit cools.

Mr. Reece's process is to distil peat in a sort of blast furnace, to the top of which a condensing worm is attached. The air supplied at the bottom of the furnace keeps up an imperfect combustion of the peat, and the products are conveyed into the worm, where they are condensed. The greasy tar which subsides is collected and heated to a temperature of 100°; it is then submitted to the action of strong sulphuric acid, and afterwards boiled in water. The paraffine collects on the surface, and solidifies as the water cools. It is now ready for distillation; and when so treated, it furnishes three products—namely, a very light oil (*eupion*), which first comes over; then a heavy oil; and finally paraffine. The light oil is separated from the mixture of the other two by decantation. When the latter is allowed to cool, the paraffine separates in the form of very minute grains; and on submitting the pasty mass to pressure in linen bags, the oil is squeezed out, and the paraffine obtained in an impure condition. The next step of the process is to deprive the paraffine of its smell and colour by the aid of chlorine and chromic acid; it is then washed, redistilled, cooled, and pressed a second time. Finally, it is submitted to the action of steam until it is perfectly white and free from odour. It is said that a thousand parts of Irish peat will furnish from ten to twelve of paraffine.

Mr. Young's process is somewhat similar to the last, but he employs Boghead coal in the place of peat. The coal is distilled from a closed retort at a low red-heat, and the products are treated in the same way as the last. One hundred parts of Bathgate coal will yield about forty of oil which is fit for lubricating machinery, and ten of paraffine.

Two years ago, a patent was obtained by Mr. Brown for the preparation of this substance from bituminous coal and bituminous schist. The process which he adopts is not essentially different from Mr. Young's.

---

[*] *Familiar Letters on Chemistry*, p. 158.

The schist is heated in an iron retort, and then exposed to a current of very hot steam. The steam carries over all the volatile matters—namely, the oils, the tar, and the paraffine. These are condensed in a proper receiver; and the semi-solid tar and paraffine are afterwards distilled, and then purified by means of sulphuric acid and oxide of manganese, or bichromate of potash. After the residue has been washed with boiling water and weak soda, it is distilled a second time; then cooled, strained, and pressed. The last purification is effected by heating it to a temperature of 400° with strong sulphuric acid. By this means, all foreign matters are destroyed; and when washed with boiling water and a solution of soda, it is allowed to set, and is then ready for the market.

Pure paraffine is obtained in the form of brilliant silvery scales when it crystallises out of boiling alcohol; but the paraffine of commerce is an amorphous substance, having the appearance of a very transparent wax. It is entirely without odour, and it does not communicate a greasy stain to paper. It is slightly flexible, and when warm may be moulded into any shape. It melts at a temperature of 110°, and distils at a red-heat, unchanged. Ether, naphtha, the volatile and fixed oils, dissolve it very readily; and it mixes freely with wax, stearine, and the fatty acids. The light emitted from it varies with the size of the wick: when a small plaited wick is used the light is clear, brilliant, and free from smoke; but when the large cotton strands of wax candles are employed, the flame is large, yellow, and very smoky. The experiments which have hitherto been made with this substance, in order to determine its illuminating power, are not sufficiently complete to enable us to judge of its value; but the candles which we have burnt are consumed at the rate of from 166 to 185 grains per hour; and the light emitted has, weight for weight of candle consumed, been exactly one-twelfth less than that of sperm.

LAMP-OILS AND SPIRITS.

Classification.—Oils are divided by chemists into two kinds—namely, *fixed* and *volatile*. The former communicate a permanently greasy stain to paper or cloth, and the latter do not. Olive oil may be mentioned as an example of one, and turpentine of the other. Again, the fixed oils are subdivided into those which become thick or gelatinous on exposure to the air (*drying oils*), as linseed and poppy; and those which do not (*fat oils*), as olive and sperm. The cause of this change will be referred to directly; but it may be remarked, in a general way, that drying oils are not adapted for combustion in lamps, on account of this disposition to become thick, and so to clog the wick.

The composition of oils is very much the same as that of the solid fats or butters: they consist, for example, of two or more ingredients; namely, *liquid oleine*, which is always present in very large proportion, as from 70 to 90 per cent.; and *solid margarine* or *stearine*. In addition to this, many of the animal oils, as sperm, whale, seal, fish, &c., contain a volatile fat, which gives them their peculiar odour. In the case of whale and seal oils, this is called *phocenine*. The relative proportion of the solid and liquid constituents of different oils is subject to great variation, and hence the difference in the property of solidifying, or becoming thick during cold weather. It must be stated, however, that all oils deposit a solid tallow-like material when they are subjected to cold; and when this deposit is very considerable in amount, as is the case with the oils of cocoa-nut, lard, olive, &c., such are not well adapted for burning in lamps unless they are used in rather warm places.

The sources of oils are very extensive; in fact, they are found in both kingdoms of nature. Animals yield to us lard and tallow-oil, sperm, whale, porpoise, seal, walrus, herring, cod, ling, and other such oils; while vegetables furnish us with the oils of almond, olive, rape, colza, cocoa-nut, linseed, hemp, mustard, poppy, cotton, teal, sesama or gingilie, castor, &c. In the former case the oil is obtained either from the cellular tissue which lies immediately beneath the skin, or else from the liver; and in the latter it is procured from the fruit, or the cotyledons of the seeds.

The modes of extraction vary with different circumstances; so much so, that it is scarcely possible to give a general description of the numerous processes adopted. In the case of lard, tallow, and cocoa-nut oils, the solid fats are slightly warmed, then enclosed in linen or horse-hair bags, and submitted to enormous pressure—a pressure of from four hundred to six hundred tons. The common fish-oils, as those of the herring, pilchard, and sprat, are obtained by piling the fish into heaps or walls, and then weighting them with stones. The oils from the livers of fish, as the cod, skate, ling, &c., are procured by boiling the livers and skimming off the oil, or else by crushing and pressing, or by allowing them to putrefy, so that the tissue may break up and let out the oil. The fat or blubber of different species of whale, porpoise, seal, dolphin, walrus, &c., is subjected to heat in iron vessels, and then submitted to pressure; and, lastly, vegetable oils are procured by first crushing the seeds, then enclosing the bruised mass in bags, and exposing to enormous pressure: this is obtained either by hydraulic power, by screws, or by wedges driven by heavy stamps. "Linseed, rape-seed, poppy-seed, and other oliferous seeds," as we are informed by Dr. Ure, "were formerly treated for the extraction of their oil by pounding them in wooden mortars with pestles shod with iron, set in motion by cams driven by a shaft, turned with horse or water-power; then the triturated seed was put into woollen bags, which were wrapped up in hair-cloths and squeezed between upright wedges in press-boxes, by the impulsion of vertical rams, driven also by a cam mechanism. In the best mills, upon the old construction, the cakes obtained by this first wedge-pressure were thrown upon the bed of an edge-mill, ground anew, and subjected to a second pressure, aided by heat now as in the first case. These mortars and press-boxes constitute what are called Dutch mills. They are still in very general use, both in this country and on the continent; and are by many persons supposed to be preferable to the hydraulic pressure."

Sometimes the crushed seeds are exposed to the action of heat and a little moisture during the operation of pressing. This facilitates the flow of the oil, and consequently makes the seeds yield a larger produce; but the oil is never so good under these circumstances, as it contains much colouring matter, together with mucilage or vegetable mucus and sugar; all of which diminish the combustibility of the oil, and render it very liable to become rancid. In the former case the oil is said to be *cold drawn*, and in the latter *hot*. The amount of oil obtained in this manner varies with different seeds, and even with the same seeds in different countries and seasons. Walnuts and hazel-nuts usually furnish about half their weight of oil; poppy seeds, nearly half; olives, about one-third; rape-seed, a third; and that variety named colza, about two-fifths; hemp-seed, a fourth; almonds, a fourth; linseed, from one-fourth to one-fifth; and the seeds of grape, or wine-stones, about one-tenth.

Olives are sometimes allowed to ferment, so as to become soft and pulpy before they are crushed and pressed. In this way they yield a larger proportion of oil; but the oil is not good, and is only fit for lamps or machinery.

We shall take occasion to notice more particularly the details of all these processes when we come to the subject of the individual oils.

Refining or Purifying.—In the state in which oils are first obtained from plants and animals, they always contain impurities, as albumen, vegetable mucus, colouring matter, sugar, rancid acids, &c. These must be removed before the oil is fit for combustion in lamps; and several processes are adopted for this purpose. Sometimes the oil is merely exposed to the action of steam or boiling water; and, after having been well agitated therewith, it is allowed to stand until the oil floats to the surface in a clear or pellucid condition: it is then drawn off by means of a syphon or tap, and so separated from the water which holds the impurities. At other times it is boiled with weak alkaline solutions, or with lime water, and allowed to repose. Dossie's process for purifying fish-oils is as follows:—To each gallon of oil an ounce of powdered chalk, and half an ounce of recently slaked lime, are added: after standing a short time, about half a pint of water is carefully stirred in, and the mixture is agitated at intervals of two or three hours, for a period of several days. At the expiration of that time, a solution of one ounce of pearlash in four ounces of water is stirred in, and the stirring is kept up at intervals for several hours: after this, two ounces of salt dissolved in a pint of water are poured in, and the mixture is agitated occasionally for the next two days. It is then allowed to stand until it becomes clear; and if the oil be not sufficiently pure and free from odour, the process is to be repeated, taking care that the quantities of the ingredients are reduced one-half.

The plan that is usually adopted for the purification of oils, is founded on the fact, that concentrated sulphuric acid, in small quantity, has the power of decomposing the impurities of oil without touching the oil itself: but in carrying out the process, care must be taken that oil of vitriol is not added in too great quantity, or allowed to act for too long a period. The process is generally conducted in the following way:—About one per cent. of commercial sulphuric acid is cautiously added, little by little, to the impure oil; in those cases where the oil clots with strong acid, as happens with linseed oil, the vitriol acid must be diluted with about half its bulk of water before it is added. The mixture is then stirred for several hours, in order that the acid may be brought into contact with all the impurities in the oil; the stirring is generally effected by means of a sort of churn or spindle with cross pieces, which is kept slowly revolving in the vat containing the mixture. In the course of a few minutes after the vitriol is added, the oil becomes discoloured; and after the agitation has been kept up for some time, the impurities clot together in the form of flakes. When this happens the oil is allowed to stand quiet; and in the course of a few hours the flakes subside, and leave the oil in a clear and almost colourless condition. The oil is now run off into vats, and boiled up with about half its bulk of water; this removes any acid that may be adhering to the oil: the fire is then withdrawn, and in a short time the oil floats upon the water, and may be run off into casks ready for the market.

Other processes have been recommended for the purification of oils; as, for example, the filtration of them through animal or peat charcoal, or the exposure of them to the action of light, or to the chemical influence of a weak solution of chloride of lime; but all these processes are more or less difficult of management, and consequently they have given place to the more speedy and certain method of refining by means of oil of vitriol. The filtration of oil through charcoal is, however, a very effectual plan for removing bad colour or bad odour.

General Properties of Oil.—Every variety of fixed oil communicates a greasy stain to paper or cloth, and has an unctuous feel. It is also perfectly insoluble in water; and when mixed therewith, speedily rises to the surface. This shows that it is lighter than water; in fact, a bottle which, when full, holds 1,000 grains of distilled water, will contain only 884 of sperm oil, or 965 of castor oil. These are the two extremes, for sperm oil is the lightest of all fixed oils, and castor the heaviest. Chemists have applied the term *specific gravity* to these numbers; and as it is found that each oil has its own particular weight, specific gravity is made the means of discovering the nature and quality of any doubtful oil.

With respect to the mode of taking specific gravity, we may state, that solids are weighed first in air, and afterwards in distilled water. The weight in air is then divided by the loss of weight sustained by the body on being weighed in water; and the quotient is the specific gravity. Liquids, such as water, spirits, ether, oils, &c., may have their specific gravity taken by weighing them in a glass globe with a narrow neck, in the manner already mentioned.

The following table represents the relative weights or specific gravities of different fixed oils:—

Sperm	884	Cherry-stone . . .	924
Tallow	900	Fish	924
Rape-seed	913	Cameline	925
Plum-kernel . . .	913	Nightshade . . .	925
Henbane-seed . . .	913	Sunflower-seed . .	926
Colza	914	Hemp-seed	926
Ground-nut . . .	915	Cocoa-nut	926
Olive	916	Walnut	926
Sessamum	916	Filbert	926
Almond	917	Anda	927
White mustard-seed .	918	Horse-chesnut . .	927
Radish-seed . . .	919	Cod-liver	928
Grape-seed . . .	920	Seal	929
Poppy-seed . . .	922	Linseed (new) . . .	930
Whale (train) . . .	923	Weld-seed	936
Black mustard-seed .	923	Orange-seed . . .	940
Walnut	923	Linseed (old) . . .	960
Cucumber-seed . .	923	Castor	965
Tobacco-seed . . .	923		

Most of the fixed oils are affected by the atmosphere—the oxygen of which they slowly absorb. In some cases the oil becomes thick; or, if exposed in a thin layer, it dries. In this manner a skin is frequently formed over the surface of the oil; and if it be left for some time in a lamp, it will assume a jelly-like appearance. Other oils do not become so thick by exposure to the air; but they acquire an unpleasant smell, and get rancid. The former is the property of the drying, and the latter of the fat or unctuous oils. These changes are due to the action of atmospheric oxygen; indeed, Saussure found that a layer of nut-oil, one-fourth of an inch in thickness, absorbed as much as 145 times its bulk of oxygen in the course of eleven months, of which quantity 142 volumes were taken up during three months' exposure to the sun. It appears, also, that it is the carbon of the oil which undergoes oxidation; and, as it were, slowly burns, evolving carbonic acid. This change is always accompanied with an elevation of temperature; and hence it sometimes happens that rags, tow, or cotton, that have been smeared over with oil, and then thrown aside as useless, have; in the course of a few days, generated heat enough to produce spontaneous combustion. Fires have frequently originated in this manner in warehouses and dockyards, where such materials have been allowed to accumulate. This points to the danger that is attendant on the careless and slovenly trick of throwing greasy rags, and other such matters, into out-of-the-way corners. Those oils which absorb oxygen with great facility, and thereby become thick, are not well-suited for combustion in lamps, unless the lamp is cleaned out every day, and a fresh wick adapted to it. The quick-drying oils are linseed, poppy, walnut, hemp-seed, and nut—all of which are employed by painters on this very account; while rape, colza, sessama or gingilie, cocoa-nut, grape-seed, cameline, sunflower, cotton, mustard, &c., only dry after very long exposure to the air; and sperm, olive, almond, seal, and whale oils are not much disposed to dry at all.

Heat and cold act upon the oils, and produce changes in them which are more or less hurtful. In cold weather—that is, at a temperature below 32°—most of the oils become thick, from the congelation of their solid constituents; and we then find great difficulty in making the oil burn in a lamp. At a temperature of 600°, or thereabouts, the several fats begin to boil; and if the temperature be carried a little higher, the oil undergoes decomposition, and gives forth a most irritating and unpleasant vapour, which is called *acroline*. At still higher temperatures, the fixed oils are resolved into combustible gases, which burn with a very bright light and a sooty flame: indeed, the object of all the arrangements for the combustion of oil in lamps for illuminating purposes, is that of bringing the oil slowly into contact with the burning wick, so as to generate the gas in question, the supply of which ought to be duly apportioned to that of the air which consumes it. When oils are heated to near their boiling-point, they frequently become thick, and acquire an increased disposition to absorb oxygen. It is on this account that inferior drying oils cannot be employed for any length of time in a lamp, without closing the channels that lead to the wick; and hence it is found necessary to clean the lamp very frequently, or else to pour away the residue of the last consumption before fresh oil is supplied. The same circumstance leads to the stoppage of the pores of the wick, and finally to a total closing of all the fine capillary channels by which the oil ascends to the flame; so that a new wick and a clean lamp are indispensable to the perfect combustion of an inferior oil.

Although the fixed oils are not soluble in water, yet they combine very readily with fluids which contain alkaline matters, as soda or potash. In this way they form white emulsions of the nature of soap; and the alkalies, or their carbonates, may be at all times resorted to for the purpose of cleaning out the half-gelatinised oils from old lamps. Ammonia, also, or strong sal volatile, is a very effective agent for removing grease from the clothes.

Concentrated sulphuric acid acts on the fixed oils in the same way as it operates on the solid fats: it first combines with the fatty acids, and then with the basic constituent to form composite acids, named sulpho-oleic, sulpho-margaric, sulpho-steric, and sulpho-glyceric acids. These are not permanent compounds, and have not, therefore, been isolated; but when they are treated with hot water, they are decomposed; and as the sulphuric acid separates, the other fatty constituents resolve themselves into four new acids—namely, metamargaric, hydromargaritic, metoleic, and hydroleic. The first two are solid, crystallisable, and partly volatile, while the last two are liquid and oily. Besides these changes, there are others effected by the action of the sulphuric acid on the sugar, mucilage, colouring matter, &c., contained in the oils; and these are so peculiar and characteristic, that they have been made the means of discovering the nature of a fixed oil. This fact was first recognised by Heidenreich of Strasburg, in 1841; but it has been greatly developed by the investigations of Penot, Marchand, and others. The mode of proceeding is as follows:—Put eight or ten drops of the oil on a white plate, and then let fall into the centre of the oil a single drop of concentrated sulphuric acid: in the course of a few seconds or minutes, the characteristic tints will be observed. Another mode of conducting the experiment is to stir the drop of acid so as to mix it with the oil. The following are the changes observed:—

(*a.*) With *olive oil* there is a yellow colour produced at the points of contact; this rapidly passes into orange, and at last into a bright chesnut-brown, while the surrounding parts of the oil gradually acquire a dirty gray, and finally a smoky tint; but there is never any shade of blue or lilac. If the mixture be stirred, it speedily becomes dirty-brown or brownish-gray.

(*b.*) *Poppy oil* immediately acquires a fine lemon-yellow colour, which soon becomes darker in some parts. The surrounding portion gradually assumes a rose tint, which speedily passes into violet, and then into a violet-blue. This requires a period of from half-an-hour to three-quarters; and finally the yellow colour becomes dirty-brown. If the oil has been kept for some months, or if it has been expressed by the aid of heat, it will then assume a greenish tint. When stirred it acquires a brownish-olive colour.

(*c.*) *Nut oil* produces almost exactly the same tints as olive oil, but it becomes brown more rapidly, so that within ten minutes it acquires a chesnut-brown colour, and the gray border changes into olive-green. If it be stirred, the oil clots and becomes dirty-brown.

(*d.*) *Castor oil* assumes a yellow tint, which slowly passes into grayish-red, and at last, after many hours, into purple-brown. When the oil is very old it becomes brown at once; and if the oil and acid be stirred, the tint is pale yellow, and then brown.

(*e.*) *Almond oil* produces nearly the same reactions as olive oil; but the surrounding tint is pale grayish, and the yellow has a greenish tint. If stirred it becomes dirty-green.

(*f.*) *Sessama, gingilie,* or *teal oil,* assumes a yellowish colour, which, in the course of a few minutes, becomes orange, and then chesnut-brown, the surrounding oil acquiring, in the course of half-an-hour, a purplish tint. If it be stirred it acquires an orange-brown colour directly.

(*g.*) *Orange-seed oil* takes on a yellow shade, which rapidly passes into brown, and then into black. If stirred, it becomes black almost immediately.

(*h.*) *The oil of black and white mustard-seed* is first yellow, then rich yellow-orange, and finally, in the course of a few minutes, brownish-black, the surrounding oil being of a greenish tint. By stirring, the dark tint is brought out almost immediately.

(*i.*) *Linseed oil* becomes rich chesnut-brown almost immediately, and it soon coagulates, or clots into a hard tenacious spot. When stirred it immediately thickens, and acquires a brownish-black appearance.

(*k.*) *Hemp-seed oil* presents nearly the same character as linseed, except that this oil assumes a greenish-yellow tint at the edges of the acid; and if stirred it acquires a greenish-brown colour.

(*l.*) *Cocoa-nut oil* acquires a pale purplish-brown colour, which gradually darkens; and when stirred it is first ochre-brown, and then deep violet-brown.

(*m.*) *Refined rape-seed oil* assumes the same appearance as the last; and it is charred, as it were, by the acid.

(*n.*) *Fresh-drawn,* or *raw rape-seed oil* becomes bright green; and then, after the lapse of ten minutes or a quarter of an hour, the tint deepens, and finally becomes olive-green or dirty greenish-brown; the surrounding edges retain a bright green colour. If the oil and acid be stirred, the tint is blueish-green, and at last olive-green.

(*o.*) *Oleic acid* changes into a sepia brown, which at length darkens almost to a black.

(*p.*) *Neat's-foot oil* becomes yellow, and then, after some time, brownish. If stirred, it changes into a dirty-brown at once.

(*q.*) *Whale* or *train oil* acquires a reddish-brown colour, with the edges of a violet tint; and, if stirred, it passes into a dark violet-brown, like that of the lees of wine.

(*r.*) *Cod* and *other liver oil* instantly changes to a rich violet, with the edges of a carmine colour; in the course of a few minutes this passes into orange, and, finally, into dark-brown. When stirred, the violet tint is very remarkable, but very transient.

(*s.*) *Seal oil* assumes a yellow colour, which passes into rich orange, and then into a blackish-brown, having a number of purple spots about the mixture. When stirred, it acquires a lively yellow tint, which soon changes to orange-brown.

If the acid be diluted with one-third its bulk of water, the reactions are slower, and the effect, in some cases, is more marked. With such a mixture, olive, almond, and castor oils show but little action; while poppy, orange, and mustard become dirty-brown; gingilie, yellowish with a pink border; linseed, brown; rape, green; cocoa-nut and refined rape, pale purple-brown; sessama, lavender; oleic acid, dirty-brown; sperm, pale lavender; cod-liver, rose, passing into rich violet, and then into brown; common whale, black-brown; seal, dirty-brown; and tallow-oil, blackish-brown.

Mixtures of the above-mentioned oils give reactions which are compounded of the preceding; and thus the fraud of adulteration may be easily detected.

Another reaction which has been noticed during the admixture of the oil with concentrated sulphuric acid, is that of a great elevation of temperature; and, as each oil produces its own amount of heat, M. Maumené has proposed that this reaction should be used as a means of discovering the quality of an oil. Maumené's results have been confirmed in the laboratory of Professor Fehling, by Faisst and Knauss, who state, that when 225 grains of oil are quickly mixed in a thin glass vessel, with 75 grains of the strongest sulphuric acid, the following are the number of degrees raised by different oils :—

Olive oil . .	68° Fah.	Rape oil . .	100° Fah.
Lucca oil . .	72° ,,	Poppy oil . .	127° ,,
Almond oil . .	72° ,,		

With an acid of 90 per cent., the rise is :—

Lucca oil . .	54° Fah.	Linseed oil . .	133° Fah.
Rape oil . . .	67° ,,		

Mixtures of these oils produce intermediate results.

Aqua-fortis, or *nitric acid*, acts with more or less energy on the fats, and converts them into other acids; one of which, namely, suberic acid, is a very constant product. But the most remarkable change is brought about in all the fats by means of *nitrous acid*, or a solution of *nitrate of mercury*. Either of these compounds will cause the fat oils to become solid; the oleine of the oil being converted into a semi-transparent jelly-like mass, named *elaidine*. This curious change is effected in olive, almond, rape-seed, hazel-nut, and other non-drying oils; but the drying oils, as linseed, hempseed, walnut, poppy, &c., are not affected by these compounds. This circumstance, and the facility with which the change is brought about, offer a means of distinguishing one kind of oil from another. M. Poutet recommends the following method for the application of this test:—Dissolve six parts of mercury in seven and a-half parts of nitric acid (sp. gr. 1·35); add two parts of this solution to ninety-six parts of oil, and shake the mixture every now and then for half-an-hour or so. If the experiment be made on pure olive oil, it will congeal in the course of seventeen hours in summer, or four hours in winter. Other vegetable oils do not combine so quickly with nitrate of mercury; and the mixture either remains fluid, or else the olive oil congeals, and the other oil separates into a distinct layer. If the oil has been adulterated with animal fat, the mixture congeals in five hours, whilst the olive oil floats on the surface, and may be decanted. MM. Boudet and Fauré have shown that this change is brought about by the *hyponitrous acid* contained in the nitrate of mercury. They therefore recommend a solution of that acid in aqua-fortis —*common nitrous acid* does very well for the purpose; and they say that each of the fat oils takes its own time to solidify, and develops its own colour. When one part of hyponitrous acid is dissolved in nine of aqua-fortis, and then added to a hundred parts of oil, the colour produced, and the times of solidification, are as follow :—

	Colour.	Time.
Olive oil . .	Greenish-blue . .	73 minutes.
Almond . .	Dingy-white . . .	160 ,,
Filbert . .	Greenish-blue . .	103 ,,
Acorn . . .	Lemon-yellow . .	40 ,,
Castor . .	Golden-yellow . .	603 ,,
Colza . . .	Yellowish-brown .	2400 ,,

Oil of poppies retards the solidifying effect, and this to so great an extent, that when present in either of the above, in no larger portion than 1 per cent., it delays the action for forty minutes.

A mixture of *equal parts of nitric and sulphuric acids* also effects the coloration of the fixed oils; and this has been shown by M. Behrens, as well as by MM. Guibourt and Reveil, to be a good means for detecting the adulteration of oils. About 150 grains of the mixed acids are added to a like quantity of the oil, and the colour, which is instantly produced, is as follows :—

Oil of Sessama	dark grass-green.
,, Olive	light yellow.
,, Linseed	brownish-red.
,, Almond	peach-blossom.
,, Castor	little changed.
,, Colza	reddish-brown.
,, Poppy	brick-red.
,, Gingilie	rich orange-brown.
,, Orange-seed . . .	rich chesnut-brown.
,, Mustard	orange-brown.
,, Rape-seed (raw) . .	orange-red, and then dirty green.
,, ,, (refined) .	yellow-red, and then purple-brown.
Oil of Cocoa-nut	pale orange-red.
,, Sperm whale . . .	orange.
,, Seal	orange-brown.
,, Cod-liver	pinkish-violet.
,, Tallow	dirty brown.
,, Neat's-foot . . .	,, ,,

M. Behrens states, that when olive oil is mixed with a fourth part of its weight of sessama oil, it takes a beautiful green colour; but Guibourt and Reveil assert, that it will discover one-tenth part of sessama in oil of olive.

Other oxydising agents, as *chromic acid*, or *a saturated solution of bichromate of potash, in oil of vitriol*, also act in a very characteristic manner on the fixed oils. This fact was first observed by M. Penot, who employed a single drop of the latter solution with twenty drops of oil, stirring them together on a white plate. The following are the effects produced :—

Almond oil .	becomes	yellowish in small lumps.
Hemp-seed oil	,,	yellow in clots on a green ground.
Rape-seed oil .	,,	,, ,, ,, ,,
Poppy oil . .	,,	,, ,, ,, ,,
Ditto (cold-drawn)		,, ,, white ground.
Castor oil . .	,,	slightly green.
Linseed oil .	,,	brown clots on a white or greenish ground.
Nut oil . .	,,	brown clots.
Olive oil . .	,,	brown.
Cod-liver oil	,,	dark red.
Whale oil . .	,,	brownish-red clots on brown ground.
Tallow oil .	,,	reddish-brown.
Neat's-foot oil	,,	brownish-red spots on brown ground.

The illuminating power of different oils varies with different circumstances, as with the temperature of the room, the size and form of the wick, and the freedom with which the oil is supplied to the flame; so that it is difficult to arrive at anything more than an approximation to the value of different oils as illuminating agents. Count Rumford estimated the relative illuminating power of different oils when burnt in Argand and in common lamps, thus—the numbers being the weights consumed to get an equal amount of light :—

Good wax, well-snuffed	100 grains.
Olive oil in an Argand lamp . . .	100 ,,
Olive oil in a common lamp	129 ,,
Rape oil ,, ,, ,, ...	125 ,,
Linseed oil ,, ,, ,, ...	120 ,,

From some experiments which have been conducted for the purpose of arriving at an approximation to the relative value of different oils, we have drawn up the following table, which represents the proportions of oil to be consumed in order to obtain a light of given value —namely, that of thirteen sperm candles, each consuming 120 grains per hour. In these experiments the same lamps were used for each of the oils, and the wick was in each case of precisely the same description; a new wick being employed for each experiment. The consumption of oil in the Argand ranged between 316 and 378 grains per hour, and that of the common lamp between 87 and 123.

	Argand Lamp.	Common Lamp.
Tallow . . .	1008 grains. . . .	1300 grains.
Sperm . . .	1029 ,, . . .	1751 ,,
Train . . .	1067 ,, . . .	1941 ,,
Olive . . .	1080 ,, . . .	2014 ,,
Seal . . .	1107 ,, . . .	1892 ,,
Sessama . .	1113 ,, . . .	1776 ,,
Poppy . . .	1119 ,, . . .	1660 ,,
Refined rape .	1134 ,, . . .	1881 ,,
Refined linseed	1231 ,, . . .	2376 ,,
Raw rape . .	1236 ,, . . .	1940 ,,
Brown rape .	1343 ,, . . .	1827 ,,
Mustard-seed .	1354 ,, . . .	2058 ,,
Fish	1362 ,, . . .	1976 ,,

From this it will appear that there is no direct relation between the illuminating power of the oil and its consumption; for in some cases the oil burns better in the common lamp than it does in the Argand, and *vice versâ:*

showing that the illuminating power is modified by circumstances. This table has been constructed on the scale of thirteen sperm candles of standard value, because they represent the light of an Argand burner consuming five cubic feet of coal gas per hour.

VARIETIES OF OILS EMPLOYED FOR ILLUMINATING PURPOSES.

Animal Oils.—(*a.*) *Sperm oil.*—This, as we have already said, is the fluid portion of the head-matter which is removed from the cranial cavity of the spermaceti whale (*Physeter macrocephalus*). The oil is usually separated from the spermaceti by cold and pressure; and after having been purified by means of a little weak sulphuric acid, or alkaline lees and water, it is sent into commerce. Sperm oil is of a pale colour; it has but little odour, and it shows no disposition to congeal in cold weather, or to resinify on exposure to the air; it is, therefore, well suited for illuminating purposes.

(*b.*) *Common whale oil*, or, as it is sometimes termed, *whale train-oil*, is derived from several species of whale; as the common whales (*Balænæ*), the finned whales (*Balænopteræ*), and the narwhales (*Monodons*). Most of the oil consumed in this country is furnished by the common Greenland whale, the *Balæna mysticetus*, large numbers of which are annually captured by the whalers of England and America in several of the Arctic Seas. They are taken in the Greenland seas; in Davis' Straits; along the coasts of Spitzbergen, Iceland, and Norway; off Labrador; in the Gulf of St. Lawrence; around Newfoundland; in Baffin's and Hudson's Bays; and in the seas northward of Behring's Straits. The *balæna* is also found in more congenial climates, as on the coast of Ceylon, and in the China Sea.

In the early days of whaling, when the animal was found in great numbers immediately around the shores of Spitzbergen, the Dutch formed a settlement on that island, and performed there all the operations of preparing the bone and extracting the oil. They gave the name of Smeerenberg (from *smeeren* to melt) to their settlement; and to so flourishing a state did the fishery arrive, that, during the busy season, every species of luxury could be obtained at the village, although it was situated within a few degrees of the pole. This was the condition of things towards the close of the 17th century. But it appears from a narrative of the voyage of Ohthere the Dane, given by King Alfred in his translation of Orosius, that the pursuit of the whale was practised by the people of Norway at least as early as the 9th century. We have no account, however, of the way in which the animal was captured, nor are we informed as to the object of the pursuit—whether it was for mere sport, or for some useful purpose. It is very probable the business of hunting the whale was not carried out upon any systematic plan, but was confined to such accidental encounters as opportunity offered. As early as the 12th century, the inhabitants of the coast surrounding the Bay of Biscay were undoubtedly engaged in the capture of the whale for commercial purposes; and they are generally regarded as the founders of this species of enterprise. At first their operations were confined entirely to the neighbouring bay; but as the whale became scarce, the Biscayan mariners extended their search farther and farther from their shores, until they reached the coasts of Iceland, Greenland, and Newfoundland. "Thus," says Mr. Dewhurst, "was commenced, in the course of the 16th century, the northern whale-fishery, as pursued in modern times. In 1594, the English made their first whaling voyage; and four years afterwards the merchants of Hull fitted out several ships for the purpose: about the same time the Dutch were tempted to engage in the trade; and soon afterwards the Hamburgers, the French, and the Danes were occupied in the same pursuit."

The whale is captured by means of harpoons, and, when dead, it is drawn to the side of the ship, and flensed or cut up. This is effected by means of spades and powerful knives, the blubber being cut into cross pieces of about half a ton each, which, after being hoisted on deck, are subdivided into small strips, and then forced into the bungholes of the storing casks. The blubber is the true skin of the animal; and it consists of a network of intersecting fibres, which enclose the liquid fat. It encompasses the whole of the body: its thickness varying from eight to twenty inches, though one foot is about the average; and a single whale will yield from twenty to eighty tons of it. The lips of the animal furnish the best kind of blubber; and they weigh from one and a-half to three tons each. The quantity of oil so obtained, amounts to about three-fourths of the entire weight of the raw blubber.

Formerly, it was the custom to extract the oil from the blubber at the places where the whales were caught, but now this process is effected after the fat arrives in this country. The operation is thus managed:—The half-putrefied fat is thrown into vats which have a wire grating at the bottom. The tissue is then broken up by pressure, and the oil runs out into a reservoir, which is placed below the vats: that which remains behind is called *finks*. After the oil has settled for two or three days, it is poured off into another vessel, and heated to a temperature of 225°. This causes the albuminous matter to coagulate, which, with the other impurities, soon subsides to the bottom of the boiler. The fire is now withdrawn, and water is poured into the vessel, in order that the dregs may be more easily separated from the oil, and may not stick to the bottom of the boiler. After standing for some time, the oil becomes clear, and then it is run off into casks. Another mode of extracting the oil is to boil the blubber with water, and to skim off the oil as it rises. The oil may also be obtained by allowing the blubber to putrefy, and thus to release the fluid fat from the cells in which it is contained. In this manner, by suspending the blubber in bags over casks, the oil gradually drips out, and is collected.

We have already said that the train-oil of commerce is chiefly derived from the common Greenland whale (*Balæna mysticetus*); but when this creature is scarce, another species of balæna—namely, the *Balæna Icelandica*, or nord-caper—is sought for; and under certain circumstances the different species of finned whale, as the *Balænoptera gibbar*, *boops*, *rorqual*, &c., and even the *Monodons* or *narwhales* may be made to yield train-oil. It is not often, however, that the whaler has an opportunity of capturing these creatures; for they are so swift and shy, that there is great difficulty as well as danger in approaching them. Occasionally they are cast ashore on the northern and western coasts of Europe; and then they become a source of great profit from the quantity of oil which they yield. Some idea may be formed of the value of these animals by the following fact:—In the month of August, 1827, a large specimen of the *Balænoptera rorqual* was found floating off the port of Ostend. It was towed into the harbour by some fishermen; and when cut up, it yielded 40,000 lbs., or 4,000 gallons of oil. The specimen measured ninety-five feet in length, and weighed about 240 tons.

Lastly, it may be stated that the several species of *dolphin* furnish abundance of oil. They belong to the whale tribe, and inhabit the seas of all latitudes; for they are found in the Arctic Ocean, the Mediterranean, the Gulf of Messina, the Adriatic, and on the coasts of China: in many of which places there are large establishments for their capture, in consequence of their furnishing an excellent oil for illuminating purposes. To this order of animals belong the common porpoise (*Phocæna vulgaris*), the round-headed porpoise, or ca'ing whale (*Phocæna melas*), and the white whale (*Phocæna leucas*); all of which yield oil in considerable quantity. The common porpoise is captured by the inhabitants of the western islands of Scotland, where it abounds; and we are told, that about eight gallons of oil are obtained from each individual. The round-headed porpoise is taken in the Shetland Islands, the Orkneys, and in Iceland; and the white whale in several localities on the shores of the North Sea.

The oil obtained from these sources, when properly purified, is very little inferior to sperm oil: it does not clog the wick, or congeal in cold weather, and it burns with a clear white flame, which is tolerably free from smell. About 20,000 tons of whale oil and spermaceti are annually imported into this country.

(*c.*) *Seal oil* is procured from several species of *phocidæ*. The common seal (*Phoca vitulina*) is captured in large numbers on the shores of Newfoundland: indeed, we are informed that, during a good year, hundreds of thousands are taken in that locality, for the sake of the oil which they yield. They are also killed on the northern coast of Scotland, in the Orkneys, Shetlands, and on the shores of Greenland. To the inhabitants of the last-named locality the seal is invaluable; for it furnishes them with food, raiment, and oil. The animal is usually captured with spears or harpoons, and sometimes it is shot. As soon as it is dead, the skin is stripped off, and then the fat is removed and boiled down in copper or iron vessels. Seal oil, like the preceding, is not much disposed to thicken; and hence it is well suited for combustion in lamps.

(*d.*) *Walrus oil* is obtained from the morse or seacow (*Tricheeus Rosmarus*), many of which are annually destroyed at Spitzbergen, and elsewhere, for the sake of the skin, oil, and teeth. We do not receive the oil into commerce in this country, and consequently have little or no opportunity of testing its value; but it appears that its qualities are not inferior to those of the last-mentioned oil.

(*e.*) *Fish oils* are extracted from the bodies and livers of fish. As examples of the former, we may mention the oils obtained from the herring (*Clupea harengus*), pilchard (*Clupea pilchardus*), and sprat (*Clupea sprattus*): all of which are procured by submitting the fish to great pressure at the time that they are undergoing the process of salting. Of the latter may be mentioned the oils of cod (*Morrhua vulgaris*), ling (*Gadus molva*), skate (*Raia batis, &c.*), turbot (*Lota vulgaris*), torsk (*Brosmius vulgaris*), &c. The oil is obtained by placing the livers in a tub which has a perforated bottom covered with small branches of trees. As the livers putrefy, the oil drips out, and is caught in a vessel placed underneath. At other times the oil is extracted by boiling the livers in an iron pot, and then squeezing them in linen bags. Cod-liver oil is not much used for purposes of illumination, as it is a valuable remedy for the cure of many diseases; but the oil of ling is extensively prepared by the poor of the Orkneys and western islands of Scotland, where it is employed as a common lamp-oil. All these oils are somewhat of a drying nature, and therefore become thick after a time; besides which, unless great care has been taken in their preparation, they are sure to have a most unpleasant, fishy, or putrid odour.

(*f.*) *Lard oil, and the oleine from tallow and other animal fats*, is obtained from the solid fats by slightly warming them, and then submitting to pressure. This oil is apt to deposit solid matter in cold weather, and thus to become thick; but the properties of the oil are otherwise very good; and, consequently, it is well suited for combustion in lamps. The *oleic acid*, which is procured during the manufacture of stearic and margaric acids for candles, is not fit for illuminating purposes; for, although it gives out a very good light during its combustion, yet it is so apt to clog the wick from the impurities which it contains, that, in the course of a very short time, the lamp ceases to burn. Were it not for this, oleic acid might be extensively employed as an illuminating agent.

Vegetable Oils.—(*a.*) *Olive oil.*—This is furnished by the fruit of *Olea Europæa*, of which there are two varieties —namely, the *longifolia* of France and Italy, and the *latifolia* of Spain. The olives are gathered as soon as they are ripe, and this takes place early in November. In France, where the best oil is prepared, the fruit is bruised in a mill directly it is gathered; it is then wrapped in a sort of matting, and submitted to pressure. The oil which runs out is called virgin oil, and is kept separate for table and dietetical purposes. The cake is removed from the press. broken up by hand, moistened with boiling-water, and re-pressed; in this manner a second quality of oil is obtained, which, on standing, separates from the water with which it is mixed. The cake that is left from this operation is called *grignon*, and, generally, it is set aside to dry, in order that it may be used for fuel; but sometimes it is submitted to fermentation, then wetted with boiling-water, and pressed a third time, by which means a third quality of oil, called *gorgon*, is procured, which is used for lamps and machinery.

In Spain the olives are allowed to ferment for a period of ten days or a fortnight before they are crushed and pressed. In this way a larger supply of oil is obtained, but the quality is very inferior to that prepared from the fresh nut. One of the reasons why this delay takes place, is, that there are not sufficient presses in the oil districts to perform the necessary work; and hence the several growers are obliged to wait their turn, and keep their olives ready for the mills. But, within the last few years, considerable improvement has been effected in this respect by the introduction of hydraulic presses; and now a large portion of the oil obtained from Spain is equal, or nearly equal, in quality to that of France and Italy.

The machinery employed by the Neapolitan peasants in the preparation of Gallipoli oil, is of the rudest kind. The olives are allowed to ripen to the fullest extent on the trees; and, as they fall off, they are collected by women and children, and carried to the mill. The oil which is expressed is put into sheep or goat-skin bags, and conveyed on the backs of mules to Gallipoli, where it is allowed to clarify by standing in cisterns which are cut out of the rock on which the town is built. When it has become sufficiently clear by the deposition of mucilage, water, and other impurities, it is run off into skins, and conveyed to oil-basins which are situated near to the sea-shore. From these it is put into casks, and exported.

According to Sieuve, olives furnish about thirty-two per cent. of oil—twenty-one of which come from the pulp (or pericarp) of the fruit, four from the seed, and seven from the woody matter.

In whatever way the oil is obtained, it must be clarified and freed from mucilage, &c., before it is fit for use. This is usually accomplished by allowing the oil to stand in a warm place for a fortnight or three weeks, during which time it deposits impurities, and becomes clear. It may also be refined by heating it for a short time with a weak solution of potash or soda, and then allowing it to stand; or it may be deprived of its acid congealable matter, by exposing it for some time to the action of a piece of lead—the bottle containing the oil and the lead being placed in a window, or other place where it will receive the direct rays of the sun. In this way the oil used by watchmakers and machinists is refined. The best variety of olive oil is called Florence oil, which is the produce of Aix, in France; while the worst is the Spanish.

In this country the price of olive oil renders it too costly for lamps; but in Italy, Spain, and France, it is extensively employed for such purposes. It burns with a clear white light, and does not emit any unpleasant odour; besides which, it is not a drying oil, and is therefore not likely to clog the wick. When it is adulterated with poppy, nut, or sessama oils, its properties are very much deteriorated.

(*b.*) *Almond oil* is extracted from the kernels of the common almond (*amygdalus communis*), of which, as in the case of the olive, there are two varieties; namely, the sweet (*dulcis*) and bitter (*amara*), both of which yield the oil of commerce. The almonds are agitated in bags, so as to separate a portion of their brown skin, then crushed in a mill, and, after being folded in canvas bags, they are subjected to pressure between cast-iron plates. That which runs over first is the best. The residue is then heated and again pressed, by which means an oil of inferior quality is procured. When first obtained, the oil is thick and discoloured; but by repose in a warm place, or by filtration through paper or sand, it becomes clear. Almonds yield from twenty-two to twenty-four per cent. of oil. It is too expensive for lamps, though its flame is very brilliant, and its other qualities are remarkably good.

(*c.*) *Rape oil* is extracted from the seeds of several species of brassica (the cabbage and turnip tribe), as the *Brassica oleracea*, *campestris*, *napus*, &c.; all of which are cultivated in this and other countries for the oil which they yield. In France a very superior rape oil, termed *colza oil*, is obtained from a variety of *Brassica campestris*, named *oleifera*. In every case the oil is procured by crushing or grinding, and pressing the seed in the way already described, and it is refined by the addition of one or two per cent. of sulphuric acid. The seeds yield from twenty-eight to thirty per cent. of oil. Most of the rape oil employed in this country is expressed here. Occasionally we receive small shipments of the oil from Belgium, France, and the East Indies; but by far the larger proportion is obtained from the seed itself, of which we import large quantities. Mr. Brotherton, who is a large oil-presser, states, that good English-grown rape yields the best kind of oil; and he recommends this fact to the notice of agriculturists, saying that as much as five quarters of seed, worth fifty shillings a quarter, may be obtained from an acre of land.

Rape oil is extensively used for illuminating purposes, both here and on the continent: in fact, it is now the usual lamp-oil of commerce. Its properties are but little inferior to those of sperm; and the only objection that can be urged against it is, that after it has once been heated in the lamp it is apt to thicken and to clog the wick. Colza oil is generally consumed in the Carcel or French lamp; but it has no very great advantages over the commoner kinds of rape oil. The crude or raw oil is not suited for such purposes, on account of the mucilage which it contains: it is of a greenish-brown colour, and has somewhat the odour of linseed oil; but when it is refined it loses both of these objectionable properties, and becomes as pale and limpid as sperm.

(*d.*) *Cocoa-nut oil* is the produce of the *Cocos nucifera*, or common cocoa-nut palm; the fruit of which is decorticated, crushed, heated, and pressed. We have already stated that the oil is imported into this country in a buttery or tallow-like condition; and that after submitting it to pressure between warm plates, the liquid oil runs out, leaving the cocinine or cocoa-nut stearine for the manufacture of candles. The elaine or oleine of *palm oil* may be obtained in a similar way; and both of the oils may be purified by means of common sulphuric acid. Cocoa-nut oil has rather a pleasant odour, and it burns exceedingly well in lamps, provided it is not exposed to too low a temperature; for it is apt to congeal by cold.

(*e.*) *Sessamum or Gingilie oil* is procured from the *Sessamum orientale*, of which there are several varieties cultivated in India for the oil which they yield. These are the *suffed-til*, or white-seeded variety; the *kala-til*, or party-coloured; and the *tillee*, or black. It is from the latter that the oil is chiefly obtained. A large quantity of the oil and seed is imported into this country, and into France for the purpose of adulterating other oils; but in India it is used very extensively as an article of diet, and also for lamps. The oil is extracted and refined in the usual way.

(*f.*) *Ground-nut oil* is obtained in large quantity from the ground-nut or seed of the Bhoe moong (*Arachis hypogæa*), a plant that is pretty extensively cultivated in various parts of India. The seeds furnish about forty-four per cent. of a clear pale-yellow oil, which is largely used as food and for lamps. Two varieties of the plant are cultivated in Malacca—namely, the white seed and the brown, both of which yield a very good oil. About eighty or ninety tons of this oil are imported into this country every year.

(*g.*) *Common nut oil* is derived from two sources—namely, the *Corylus avellana*, or common hazel-nut; and the *Juglans regia*, or common walnut. The former produces about half its weight of oil, and the latter about one-third. The oil is not much used for lamps on account of its energetic drying properties: indeed, it is more apt to resinify and clog the wick than linseed; but it is largely employed for adulterating other oils.

(*h.*) *Poppy oil* is procured from the seeds of several species of poppy, as *Papaver somniferum*, *bracteatum*, *orientale*, &c. The plant that yields the largest amount of oil, and which is usually cultivated for this material, is a variety of the *somniferum*, named *nigrum*, from the black colour of the seeds. Large quantities of this oil are expressed every year for the purpose of adulterating other oils. It is clear, sweet, limpid, and almost colourless; but the great objection to its use as a lamp-oil, is its disposition to dry.

(*i.*) *Linseed oil* is extracted from the seeds of the flax plant (*Linum usitatissimum*), which yield from twenty-two to twenty-seven per cent. of oil. If the seeds be crushed and pressed at an ordinary temperature, they yield not more than eighteen or twenty per cent.; but the oil is of a pale colour, and is thought by some to be of superior quality to the hot-drawn. A large quantity of linseed is cultivated in this country, but the great bulk of the seed used by the oil-presser is imported. The seed is crushed, ground, and pressed in the usual way; and the oil is refined by means of dilute sulphuric acid. Linseed oil is not usually burnt in lamps, on account of its drying properties; but if the wick be changed every day, and no more oil is placed in the lamp than is necessary for one night's consumption, it will be found to burn very well, and to give a very clear light. By boiling or heating, it acquires increased consistence, and is then more apt to dry.

(*k.*) *Hemp-seed oil.*—This oil is produced from the Indian hemp (*Cannabis sativa*), the seeds of which yield about one-third their weight of oil. The oil has a disagreeable smell, and is not much employed for illuminating purposes, except by the poorer classes of India.

(*l.*) *Cameline or Dodder oil* is extracted from the seeds of the *Camelina sativa*, a plant that grows abundantly in Canada, where the oil is used as a common lamp-oil. It is also employed for the same purpose in several parts of Germany.

(*m.*) *Cotton-seed oil* is thought to be as good as rape for lighting purposes: indeed, small quantities of the oil have been expressed for several years past, and used in this way; but the value of the material has not been fully realised until within the last few years. At the Exhibition of 1851, specimens of the oil and cake were shown by Mr. Burn of Edinburgh, and by M. De Géminy of Marseilles, to both of whom prize-medals were awarded. It appears that, as early as 1785, the importance of this material was perceived by the Society for the Encouragement of Arts and Commerce, for they offered a prize for its manufacture on a large scale; but it does not seem to have been taken up extensively, perhaps because of the difficulty in purifying the oil. It has, however, been extracted for some time in India, America, and Egypt. Of late years the oil has attracted attention, and means have been devised for its purification. This is of importance, for very large quantities of cotton-seed are destroyed every year: in fact, more seed is always produced than is required for the next year's crop, and hitherto this excess has been thrown away as useless. At present it is exported to this country, or to France, where it is crushed and pressed. Mr. Burn of Edinburgh, and M. De Géminy of Marseilles, have each large mills for the expression and purification of the oil. When first expressed it has a dirty-brown colour; but, by rectification with sulphuric acid, it becomes clear, and assumes a pale amber tint, in which condition it is well suited for combustion in lamps. The botanical name of the plant which furnishes the seed is *Gossypium herbaceum*. It is cultivated in India, Syria, Asia Minor, along the Mediterranean, and in America.

(*n.*) *Mustard oil.*—This is procured from the dross or siftings of black and white mustard-seed (*Sinapis alba* and *Sinapis nigra*), both of which are cultivated very extensively in this and other countries, for the manufacture of mustard-flour. The siftings furnish about forty per cent. of a dark-brown oil; the seeds themselves yield from eighteen to thirty-six per cent. In India an excellent oil, called *shersha*, is expressed from several species of *sinapis*, as the *toria*, *glauca*, *nigra*, &c. All these varieties of mustard oil are very dark-coloured when first expressed, and they have the peculiar pungent odour of mustard. Both of these properties are, however, removed by the process of refining; and then the oil may be used in the place of rape or colza for illuminating purposes. Usually the oil is employed for the adulteration of the latter.

(*o.*) Besides these oils, many others are employed in various parts of the world, for the purpose of giving light; thus, the oil of plum-stones (*Prunus domestica*), and of raisin-stones, or wine-stones (*Vitis vinifera*), are used in Spain, Germany, and France. The oils of belladonna-seed (*Atropa belladonna*), tobacco-seed (*Nicotiana tabacum et rusticum*), and henbane-seed (*Hyoscyamus niger*), are used in Swabia and Würtemberg. Oils are also extracted from the beech-nut (*Fagus sylvatica*), sunflower-seed (*Helianthus annuus*), weld-seed (*Reseda luteola*), orange seed (*Citrus aurantium*), cucumber-seed (*Cucurbita pepo*), &c.; and in India there are numerous plants, which yield abundance of oil that is well suited for illuminating purposes. Among these may be mentioned *ramtil oil*, or, as it is sometimes named, *teal oil*, from several varieties of *Gurzotia*, as *Gurzotia oleifera* and *Abyssinica*, both of which yield about eighty-four per cent. of oil that is very similar to sessamum oil; *Poon-seed oil*, or *Pinnacottay oil*, from the seeds of *Calophyllum inophyllum*, which furnish about sixty per cent. of it; *Napala oil*, from the seeds of *Jatropha curcas; Mulu unnay oil*, from the seeds of *Argemone Mexicana; Cheeroojee oil*, from the fruit of *Chirongia sapida*, or *Buchanania latifolia*; oil of *Kossumba*, or *Koosm oil*, from the seeds of the safflower (*Carthamus tinctorius*), which yield about twenty-eight per cent. of it; *Kanagu nune*, or *Kurrunj oil*, from the seeds of *Pongamia glabra*, or *Galedupa arborea; Mooncela oil*, from the seeds of *Dolichos biflorus* (?); *Caju apple oil*, from the seeds of *Anacardium occidentale; Lambolee oil*, from the seeds of *Bergera koenigii; common jungle oil*, from the seeds of *Ricinus communis;* and several other varieties, the sources of which are not well known. Many of these oils are admirably well suited for combustion in lamps; and, if there were a sufficient demand for them, they might be furnished to commerce in considerable quantity. "The knowledge of this circumstance," say the jurors, in their report on the products of the Great Exhibition, "is of great practical value, because, not only is it possible that by the introduction of improved machinery, or by increased facilities of conveyance, their price may be reduced; but the very existence of such substances tends to equalise the market value of those oils now generally employed. And should, at any time, accidental circumstances cause the price of the latter to advance, these substances would then be most advantageously introduced, and would, probably, ere long, altogether supersede the oils in the place of which they had been originally imported."

Volatile Oils.—(*a.*) *Oil of turpentine, or camphine*, may be obtained from the oleo resinous exudation of various species of pine, larch, &c., as the Scotch fir (*Pinus sylvestris*), the cluster pine of Bordeaux (*Pinus pinaster*), the swamp pine of America (*Pinus palustris*), the frankincense pine of Virginia (*Pinus tæda*), the silver fir of Germany, Siberia, and Switzerland (*Abies picea*), the common larch of the continent (*Larix Europæa*), and the turpentine pistacia of Syria and Greece (*Pistacia terebinthus*). The oleo-resin is imported into this country under the names of common turpentine, Bordeaux turpentine, Strasburg turpentine, and Venice turpentine. The first of these yields the great bulk of the turpentine of commerce; it is the produce of the *Pinus palustris*, and perhaps, also, of the *Pinus tæda*, and is chiefly imported from the United States of America. The method which is generally adopted for procuring this oleo-resin is as follows:—The tree is selected, and a hollow is cut into it, a few inches from the ground; the bark is then removed for a space of eighteen or twenty inches above the hollow; and for several months—namely, from March to October—the turpentine flows from the divided sap-vessels into the excavation. At convenient times the semi-fluid matter is scooped out, and put into casks; and, when these are full, they are sent away for exportation.

Volatile oil of turpentine is procured from the oleo-resin by distilling the latter with a due proportion of water. The turpentine and water come over together, forming a milky liquor, which, on standing, separates into two layers, of which the turpentine is the uppermost. These are easily decanted or poured off one from the other; that which remains in the still is resin. Common American turpentine yields from fourteen to sixteen per cent. of spirits.

The turpentine which is thus obtained is not sufficiently pure for combustion in the camphine lamp, for it contains a small proportion of resin, which is very apt to clog the wick. This impurity is easily removed by a second distillation, and the product which is thus obtained is sent into commerce under the name of *camphine*. It is a colourless, limpid, and very inflammable liquid, that burns with a remarkably sooty flame. Its specific gravity is 870, and it boils at a temperature of 314° Fah.; though, if water be present, it will distil at as low a temperature as 212°. Turpentine freely absorbs oxygen from the air, and is converted into an oleo-resin. In the course of four months it will take in about twenty times its bulk of atmospheric oxygen. The change which is thus produced in the liquid, renders it unfit for combustion in the camphine lamp, in consequence of the resinous oxide having a tendency to clog the wick. To remedy this evil, the liquid must be redistilled, and the camphine should be preserved in well-corked vessels.

The light that is emitted from turpentine when it is properly burnt, is remarkably vivid and white; in fact, the illuminating power of camphine is nearly twice as great as that of sperm oil; and if it were not for the liability of the combustible to evolve smoke, it would be one of the most valuable of all illuminating agents. This, indeed, is the great objection to its use; for it is found that the slightest mismanagement of the flame causes the production of a cloud of blacks, which settle upon the furniture and dress, and damage them irreparably. To obviate this as far as possible, the chimney of the camphine lamp is made very tall, and thus a strong current of atmospheric air is secured to the flame.

A mixture of turpentine and alcohol has been used in France for some time past, under the name of "*Eclairage au Gaz Liquide.*" The lamp which is employed for the combustion of this material, was originally contrived by Lüdersdorff; it is called a vapour-lamp, because it is constructed so as to convert the volatile liquid into vapour, which burns as it escapes through a number of fine orifices. By diluting the turpentine with alcohol, its liability to smoke is considerably diminished; but still there is a large quantity of soot evolved when the mixture is burnt in an open lamp without a glass. The French liquid has a very peculiar odour; it is clear and limpid like water, and has a density of 823. Its boiling point is 190° Fah. When mixed with water, it becomes turbid and milky from the separation of the turpentine, which soon floats to the surface and forms an oily layer, the bulk of which is about half that of the original liquid. From this it would appear that it consists of about equal parts of strong alcohol and turpentine, the mixture being doubtless effected by distilling the two liquids together; for if alcohol and turpentine are merely shaken up together, they will not unite in this proportion: indeed, 100 parts of spirits of wine, of specific gravity 840, will only take up 13½ of turpentine; and alcohol of much less density (830) will not take up more than 20 per cent. of it.

When the French liquid is burnt in an ordinary open lamp, at the rate of 138 grains per hour, it gives a light which is about two-thirds as great as that of a standard sperm candle.

The great objection to the use of this liquid is its liability to explode when its vapour becomes mixed with atmospheric air. In consequence of this property, the greatest caution is necessary in manipulating with the fluid; for should an explosion take place, the most dangerous results might follow. We are not likely to employ the mixture in this country, on account of the high price of spirits of wine; but in France and Germany, where alcohol is comparatively cheap, the fluid is often used as an illuminating agent at railway stations in country towns.

(*b.*) *Coal-naphtha.*—When coal is distilled for the manufacture of gas, a tar is obtained which is the source of common naphtha. The tar itself is a very complex material, for it contains a number of oily acids, alkalies, and neutral bodies. As it comes from the gas-works, it is a thick, dark liquid, of a most offensive odour. To extract from it its various constituents, it is put into large iron retorts or stills, and submitted to distillation; that which comes over first is of an aqueous nature, and smells strongly of ammonia; then follows a brownish oil, which floats on the preceding. After a time, a denser or heavier oil begins to make its appearance; and when this happens, the receiver is changed, and the first product is set aside for the manufacture of light oil or crude naphtha. The coal-tar generally yields from four to five per cent. of this fluid. As the distillation of the tar proceeds, a heavy oil, which falls to the bottom of water, and is hence termed dead oil, comes over. This is used, under the name of creosote, for the preservation of timber. After this a yellowish semi-crystalline fat, called naphthaline, makes its appearance; and, finally, a more solid material, named paranaphthaline, distils over. That which remains in the retort is pitch.

The crude coal-naphtha is rectified either by distilling it a second time, or by driving steam through it and collecting the condensed products. In this way it is separated from another portion of heavy oil which remains in the still.

The light naphtha thus obtained is sent into commerce, and sold for about 2*s.* 4*d.* per gallon, for combustion in the common vapour-lamps which are so frequently to be seen in the streets of London, lighting up the stalls of the poor tradesmen. In this condition it is an amber-coloured liquid, of a powerful gas-like odour, and spirituous appearance. It has a density of from 860 to 900—usually it is about 887. It floats on water, like turpentine, and becomes darker coloured by exposure to the air. It mixes very freely with wood-spirit or with spirits of wine; and may thus be burnt like the last-named liquid, in an ordinary lamp.

The light naphtha is further purified for commerce by agitating it with a little oil of vitriol, then washing with water, and redistilling. In this condition it is sold as rectified naphtha, and is used for combustion in the naphtha spirit-lamps which have a flat wick and oval glass.

Mr. Mansfield has shown that light coal-naphtha contains a number of volatile oils, which may be separated from it by fractional distillation. One of these—namely, benzole—is of great importance. It is procured by boiling the naphtha in a retort, to which there is adapted a worm which coils through a vessel of boiling water; the worm is so constructed that all the vapour which condenses in it shall run back again into the still, while the uncondensed vapour (that of benzole) passes on into another receiver, where it is cooled and collected. The benzole thus obtained is rectified a second time in a similar apparatus, the temperature of the worm being kept at about 176° Fah. In this way a large proportion of volatile oil is obtained, which is further purified by agitating it with one-fourth its bulk of strong sulphuric acid, or, better still, with about one-tenth of strong nitric acid; and then, after separating the nitric acid, it is agitated with oil of vitriol as before. The naphtha is now to be decanted and distilled a third time. If it be required to have the benzole perfectly pure, it is submitted to a cold of 4° Fah. This is produced by mixing salt and snow together. The benzole freezes, and leaves its impurities in a fluid condition, from which it may be separated by means of a filter.

The use of sulphuric acid in this process is to remove all the basic substances, and to oxydise the brown colouring matter of the naphtha; the nitric acid assists the oxydation, and at the same time forms a small quantity of nitro-benzole, which gives a fragrant, almond-like odour to the product.

Benzole is a limpid colourless liquid, of a rather ethereal odour; its density is 850—consequently it floats on water. It boils at a temperature of 177° Fah., and gives off a vapour which is very inflammable, burning with a sooty flame. It solidifies at the freezing-point of water, and then looks like camphor. So volatile and combustible is the liquid, that when a current of hydrogen gas is passed through the fluid, or through a sponge moistened with it, the gas will burn with an intensely white light. Atmospheric air charged with the vapour also burns with a smoky flame and a bright light: the flame is sometimes of a violet-blue colour when the apertures of the jet are very small.

Benzole mixes freely with alcohol or with wood-spirit, and the compound so formed burns in common lamps with a very powerful light. It is necessary that the mixture should be made with proper proportions, or else the light of the flame is not good; for if there be too much spirit the light is blue, and if too little it is smoky. The mixture which is found to give the best results, is about one part benzole and two of spirit, of specific gravity 840. This mixture, when burning at the rate of 160 grains an hour, gives a light of from one-and-a-half to two sperm candles.

The extreme volatility of benzole gives to coal-naphtha the property of naphthalising air or bad gas; for if a little of the liquid be placed in the gas-meter, or in a chamber containing some pieces of sponge through which the gas passes, it will acquire increased illuminating powers. Mr. Lowe, of the Chartered Gas Company of London, has taken out a patent for this mode of naphthalising gas. Beale's lamp is also a contrivance for naphthalising atmospheric air. It consists of a cup of naphtha, through which a stream of air is made to pass; and to facilitate the volatilisation of the naphtha, a hot cap is placed over the cup, so as to communicate its heat to the air and liquid. The other constituents of coal-naphtha are not so volatile as benzole, and hence they are not fit for the purpose of naphthalising. Mansfield states, that the oil which distils over from the crude naphtha at a temperature of 230°, will take fire at its surface; but it yields so little vapour to cold air, that the latter, when passed through it, burns with but a feeble blue flame; and the oil which distils at a temperature of 300° is still less inflammable, for it will not take fire at the surface, or furnish any combustible vapour to atmospheric air. In these respects it resembles turpentine, which requires a heat of 314° Fah. to boil it.

A fluid like coal-naphtha is also obtained from the distillation of certain oily matters, or petroleums, which exude from the earth. In many places in the neighbourhood of the Caspian Sea, in Ava, at the Tegernsee in Bavaria, at Amiano in Italy, at Neufchatel, at Saint Zibio in the Grand Duchy of Modena, at Clermont and Gabian in France, at Val di Noto in Sicily, at Rangoon, Barbadoes, Trinidad, Lake Geneka in New York, and many other places, an oily matter called rock-oil oozes out of the ground, and is collected in pits dug in the earth to receive it. When distilled, it furnishes a volatile oil called naphtha, of which Persian naphtha may be taken as a good example. It is colourless, limpid, very combustible, and burns with a sooty flame. In some places it is used for illuminating purposes.

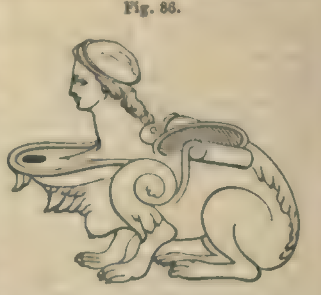
(*c.*) *The Oil of Fermented Liquor, Oil of Grain, or Fusel-oil.*—In the process of fermentation, all the saccharine fluids produce a volatile oil, which can be separated from the spirit by distillation. Pellitan, in 1825, first noticed this fact; and as he obtained the oil from spirit of potatoes, he called it potato-spirit oil. It was subsequently examined by Dumas (1834); and in 1839 it was investigated by Cahours. More recently Buchner obtained it from corn-spirit. For a long time it was obtained as a waste product by Mr. Bowerbank, a rectifier of London, who used it in his manufactory as an illuminating agent. The oil is procured at the end of the process for rectifying spirit. In its raw and impure condition it is usually called *faints*. It has the odour of bad whisky, and contains alcohol, and various fatty acids. By washing with water, then distilling with carbonate of potash, and, finally, with chloride of calcium, it is obtained in a tolerably pure condition. Five hundred gallons of corn-spirit yield about one gallon of oil. In its pure state, the oil has a peculiar ethereal odour, which, when inhaled, is rather unpleasant and irritating to the throat. Its specific gravity varies from 823 to 840; it boils at 268°, and emits a combustible vapour. The oil is not soluble in water, but it mixes with alcohol and wood-spirit in all proportions. It burns in an ordinary open lamp, with a clear and smokeless flame—the light of which is tolerably intense. A lamp that consumed the oil at the rate of 278 grains per hour, gave a light that was about half as good again as that of a standard sperm candle. At present the oil is in demand for the manufacture of artificial essences, and consequently it is too expensive for combustion in lamps.

LAMPS.

History and General Principles of the Subject.—It has been already stated that the employment of lamps can be dated back to a very early period; indeed, it is generally thought that they were invented by the Egyptians, who not only used them for common illuminating purposes, but also placed them in the tombs of the dead as emblems of mortality. The ancient Greeks were likewise accustomed to the use of lamps, which we have every reason to believe were fed with a vegetable oil. Herodotus alludes to this fact; and it is further evidenced in many devices that we find sculptured in some of the most ancient Greek vases; but it was centuries after that before the Romans began to employ lamps, and then they were only used in the houses of the rich, or upon occasions of special festivity. That most of the classical nations have been accustomed to place lamps in the sepulchres of the dead is an instructive fact; for, although various motives have been assigned for the custom, there can be no doubt that it was intimately connected with their belief in the existence of a soul, and that it was meant to typify the departure of the spirit or vital fire from its frail tenement of clay. This is clearly set forth in many of the beautiful devices which adorn the funereal lamps of the early Greeks, where the immortality of the soul, and its departure from the body, is represented by the escape of a butterfly from an apparently dead chrysalis. The testimony of Pliny, St. Augustine, and others, has induced a belief, that in many cases the sepulchral lamps were constructed so as to burn for ever; and some remarkable instances have been cited in which the lamps were said to have been found burning centuries after the tomb had been closed up; but none of these are sufficiently well authenticated, notwithstanding that Liceto and other authors have taken great pains to establish their truthfulness.

It is very probable that the earliest lamps were not made of any set form, but that the fat or oil was placed in any convenient vessel, and burned by means of a bundle of rushes or dried moss. As civilisation advanced, and the necessity for artificial light increased, attention would naturally be directed to the form best suited to the wants of the people: and it is very likely that at first the lamp was nothing more than a circular vessel or saucer containing the combustible material. Lamps of this description are still employed on the continent for purposes of general illumination. It is thought by some persons that the lamps of the virgins alluded to in the Gospel of St. Matthew (chap. xxv.) were merely rods of porcelain or iron covered with cloth, and steeped in oil or fat, and that the same kind of lamp or torch was used by the soldiers of Gideon; but we have no positive testimony in support of such an opinion, although there is plenty of evidence to show that lamps trimmed with oil were in use long before that time.

Fig. 86.



The next improvement in the form and construction of the lamp is to be seen in the ancient lamps of Herculaneum and Pompeii. Examples of these are to be found at the Louvre, the British Museum, the Vatican, and, indeed, in almost every considerable museum in Europe; but the finest specimens belonged to the king of Naples, who had a collection of such things at Portici; in fact, in that museum there is a large collection of lamps taken from the buried cities of Pompeii and Herculaneum. Besides which, Liceto, Bartoli, and Passeri have published descriptions and drawings of many hundreds of such lamps that were in the museums of Italy during the 16th century. The common form of all of them is that of an elongated vessel, like a boat, having the wick at one end (Figs. 86, 87, and 88); at other times it was a simple disc, with a hole for the wick on one or both sides, and an aperture in the centre for supplying the oil (Fig. 89). Lamps of the former description are still used by the poor of the Orkney and Shetland Isles.

Fig. 87.

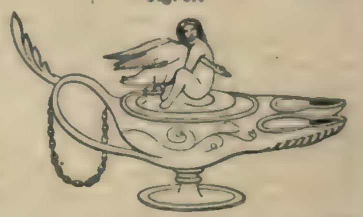


Fig. 88.

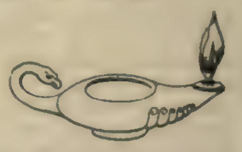
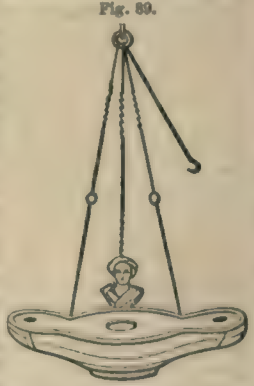


The material of which the Greek and Roman lamps were composed, was chiefly *terra-cotta*, though some of the better sort were made of bronze, and even of silver and gold. A few ancient lamps of iron have also been discovered, but they are comparatively rare, perhaps because of the perishable nature of the metal. In the museum at Portici there are several iron lamps, together with one of glass, all of which were taken from the ruins of Herculaneum.

Fig. 89.



Much ingenuity was exhibited by the Greeks and Romans in the construction and ornamentation of the supports (the λυκνουκοι, *lampadaria* or *candelabra*) which held the lamps. At first these were composed of cane; and the Greeks, in all their designs, never lost sight of this fact; consequently we find a variety of vegetable forms blended with the stiff reed, giving it lightness and elegance; the twining ivy and the graceful acanthus were frequently associated in this manner. With the Romans, however, the usual support was a tripod resting on lions' feet.

At a very early period it must have been observed, that when an attempt was made to enlarge the wick beyond a certain point, the flame became dull and smoky. To remedy this, it was customary to split the wick up into a number of small flames, each of which would allow the atmosphere to play freely around it, and thus to keep up a tolerably good combustion. There is no doubt that this device was well known to the ancients (Fig. 88), though it is generally considered, that Dr. Franklin was the first to show, that the same quantity of cotton divided into two wicks, gives a better light than when it is used as one; but the difficulty which presents itself in the employment of such a contrivance, is that of keeping the wicks equally well trimmed. To obviate this, the flat wick was invented; and thus a thin sheet of flame was produced, which allowed of much more perfect combustion. Nevertheless, with all these improvements, the light of the lamp could not be increased beyond a certain point, without its becoming dull and the wick sooty; and consequently, for many years the lamp was rarely used in the apartments of the rich, for fear of its doing harm to the walls and furniture by its great tendency to smoke.

In 1780, however, as we have already said, a great change was effected in the art of illumination by the discovery of M. Argand of Geneva, who found, that whenever a due supply of atmospheric air was furnished to the inside as well as the outside of a flame, the combustion of the oil might be kept up to any amount without danger from smoke or bad smell. The plan which he adopted for accomplishing this was very simple. He made the wick circular, and placed a glass around it so as to secure a strong current of atmospheric air to both sides of the flame. We shall have occasion to describe the details of his contrivance when we come to the subject of the various Argand lamps at present in use. All subsequent improvements on this invention of M. Argand, have been with the view of adjusting the wick, of regulating the supply of oil, of doing away with the shadow cast by the reservoir, and of directing the current of atmospheric air into the body of the flame. The first object was accomplished by means of a rack and pinion, or by a point working in the thread of a screw; the second by various forms of fountains, syphons, and, in the Carcel lamp, by means of a piston which is worked by machinery. The wick has also been modified in its construction so as to suit the condition of the oil; it is made of fine web when the oil is very fluid, and of coarse web when it is thick. The third object has been accomplished by giving the reservoir an annular form—this was Count Rumford's invention—or by placing it above the level of the flame, as in Parker's lamps; and the fourth, by contracting the glass immediately around the wick, or by putting a metallic disc into the centre of the flame, as in the Vesta lamp; or by dropping a brass nipple over it, as is the case with the solar lamp. All these contrivances increase the supply of air; and, by breaking its course, they cause it to impinge upon the body of the flame.

For the combustion of volatile oils and naphtha, lamps of very different construction are required; especially in those cases where the oil or spirit is to be consumed in a gaseous form without the aid of a wick. We shall describe these lamps, which are of comparatively modern invention, when we speak of Beale's, Holladay's, and Lüdersdorff's lamps.

With all lamps, however, the great principle that is to be kept in view is, so to adjust the supply of atmospheric air to the combustible, that, on the one hand, the flame shall not evolve smoke, and, on the other, it shall not be cooled or over-burnt; for, in the one case there is too little atmospheric air, and in the other there is too much.

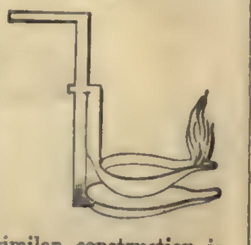
Management of Lamps.—Lamps will not burn in a satisfactory manner if they are not kept clean and well trimmed; for, in the first place, nearly all the oils which are made use of at the present time are, more or less, drying in their nature, and consequently they are apt to become thick in the lamp, and to clog its several apertures. Whenever this occurs, the lamp ceases to burn; and there is no help for it but a good cleaning. This is accomplished by draining out all the oil as completely as possible, then charging it with a strong solution of soda or pearlash, which combines with the oil and forms soap. This solution ought to remain in the lamp for twenty-four hours, and it should be frequently agitated; but care should be taken not to spill any of the liquor over the paint or lacquering of the lamp, for fear of dissolving it off. After it has stood in this way for the necessary time, the soapy liquid may be run out, then washed clean away with warm water; and, finally, the lamp is to be well dried. Some of the very common oils are so liable to resinify, that it is necessary to change the wick every day: this is the case with the oils that are used in Parker's hot-oil lamp, and consequently it is trimmed with a very short wick. In the second place, the wick should be properly attended to: if a solid wick is used it should not be twisted too tight, for fear of stopping the capillarity of the oil; nor should it be too loose, for then it is apt to accumulate soot. If the Argand, or hollow wick, be employed, it should be selected with due regard to the quality of the oil; for a thick or fatty oil requires a coarse texture, and a very fluid oil a fine one. The top, or carbonised portion of the wick, should always be removed immediately before the lamp is lighted; for this is so changed by the action of heat, that the oil will not rise in it; indeed, the common oils are so disposed to char and clog this portion of the wick, that it sometimes requires removal several times in the course of an evening. The wick should be cut perfectly level, or the flame will be irregular, and will smoke. Lastly, in cold weather it is advisable to warm the oil before the lamp is lighted.

The relative Illuminating Power and Economy of different Lamps.—This is a subject which has not been well investigated; for the difficulties connected with it are extremely great. At the Exhibition of 1851, there were forty-nine lamps sent for examination; but the jurors declared that it was a matter of impossibility to test their value. M. Peclet is nearly the only person who has devoted attention to this subject; and the following table is constructed in great part from his investigations:—

Lamps.	Consumption per hour.	Luminosity in sperm candles of 120 grains.	Relative power for equal weight.
1. Vesta lamp without button (camphine)	140 grains	2·6	185
2. Vesta lamp without button (with coal-naphtha)	136 ,,	2·0	147
3. Common Argand . .	350 ,,	4·0	114
4. Carcel lamp	630 ,,	7·0	111
5. Sinumbra, with lateral fountain	270 ,,	2·9	109
6. Thilorier's or Parker's lamp	767 ,,	7·6	99
7. Sinumbra, with fountain above	645 ,,	6·3	98
8. Common sinumbra . .	645 ,,	6·0	91
9. Gerard's hydrostatic .	521 ,,	4·5	86
10. Common open lamp . .	103 ,,	0·8	77
11. Eclairage au gaz . . .	343 ,,	2·1	61
12. Fountain lamp, with flat wick	165 ,,	0·9	54
13. Dome Argand . . .	400 ,,	2·1	52

Varieties of Lamps.—These are so exceedingly numerous, that it is not possible, in a work like the present, to give anything more than a very general account of the most important. Indeed, there are but few really distinct principles involved in the construction of lamps, notwithstanding that there are so many modifications in their form and arrangement; we shall have no difficulty, therefore, in understanding the construction of any lamp, after we have become acquainted with the following varieties. It is proper to add, that we are indebted to the *Encyclopædia of Domestic Economy* for many of the illustrations which we are about to offer, and that the reader will therein find a very good description of the lamps now in use.

Fig. 90.



1. *Common Oil Lamp, without any Glass.*—Of these there are several:—

(*a.*) *The Common Lamp of the Shetland and Orkney Islands* (Fig. 90).—This is contrived for the combustion of common fish-oil, and the wick that is used is nothing more than a bundle of dried rushes. A lamp of similar construction is used by the Esquimaux, who employ a wick of dry moss.

(*b.*) *The Common Street Lamp* (Fig. 91) was once to be seen at the stalls of poor tradesmen; though it is now almost entirely displaced by the common naphtha lamp. It is a tin vessel, with one or two spouts emerging from the sides close to the bottom. These are packed pretty tightly with cotton wick; and being constructed on the principle of the bird-fountain, the oil flows very freely to the top of the wick, but does not run over.

Fig. 91

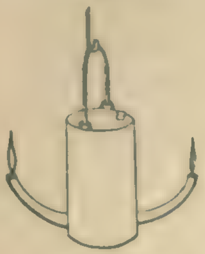


Fig. 92.

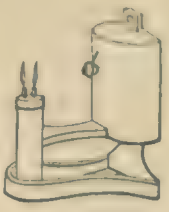
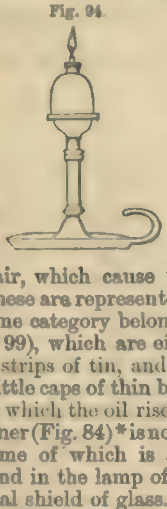


(*c.*) *The Fountain Lamp* (Fig. 92) is constructed on nearly the same plan as the last; and, as the reservoir for the oil is above the level of the wicks, the flame burns with the same brilliancy as long as any oil remains.

(*d.*) *The Common Domestic Lamp* (Figs. 93 and 94) is made to fit a candlestick. It is a very economical lamp; though, from the circumstance that the flame is situated at a considerable distance above the level of the oil, there is some difficulty in getting the lamp to burn when the oil is at all thick, or when the wick is clogged by age.

Fig. 93.

Fig. 94.



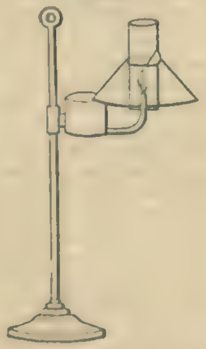
2. *Common Lamp with a Glass or Shade.*—Most of the preceding may be improved by surrounding the flame with a glass, to keep off the currents of atmospheric air, which cause the light to flicker. The principal of these are represented in Figs. 95, 96, and 97; and to the same category belong the floating night-lights (Figs. 98 and 99), which are either pieces of waxed wick supported on strips of tin, and kept floating by means of cork, or else little caps of thin brass, pierced with a hollow glass tube, in which the oil rises and burns. The safety-lamp of the miner (Fig. 84)* is nothing more than a common lamp, the flame of which is surrounded by a shield of wire gauze; and in the lamp of Upton and Roberts there is an additional shield of glass.

3. *Common Lamp, with Oxydator.*—It is found that when a current of atmospheric air is made to impinge on the flame of a common lamp, the light is much more steady and brilliant. Various contrivances have, therefore, been adopted for the purpose of effecting this; as, for example, the bending in or contracting of the glass immediately around the flame (Fig. 100); or the fixing of a metal or mica disc around it (Fig. 101); or, better still, the dropping of a perforated nipple over the flame, as is seen in Fig. 102. The last constitutes the principle of the solar lamp, to which we shall have occasion to refer by-and-by. It was, we believe, first contrived by Mr. Roberts, the miner, and was applied to his form of the improved Davy.

Fig. 95.

Fig. 96.

Fig. 97.



It will be evident, on inspecting the different lamps we have yet described, that the air supplied has access only to the exterior of the flame. Hence the interior of the flame is necessarily cooler than the exterior, and therefore tends to diminish the intensity of the whole light produced. This effect may be well noticed in a common tallow candle, when the wick has been allowed to burn for a long time without being snuffed. If, however, a supply of air could be afforded in the centre, the light would be at once increased. A patent was taken out for a plan of this kind, applicable to candles; but it was never extensively adopted. It was on the same principles as those on which the following lamps are constructed.

4. *The Argand Lamp.*—This differs from all others, in the circumstance that the wick as well as the flame is hollow; and it is so contrived that a current of atmospheric air plays on both sides of the flame, and so increases its brilliancy. There are several modifications of this lamp, of which the following are the most important:—

Fig. 98.

Fig. 99.

(*a.*) *Common Argand Lamp* (Fig. 103), which consists of a vase, *a*, to hold the oil; a cistern, *b*, to supply the burner; and an arrangement, *c*, for adjusting the hollow wick, and allowing a supply of atmospheric air on both sides of the flame. The oil is put into the vase *a*, by unscrewing it from *b*, and then running in the oil through the hole *d*, or else through the aperture in the bottom, which is usually closed by the plug *f*. The hole *d* is then closed by drawing up the handle *g*, which communicates with a sliding tube *h*, and the vase is returned to its place on *b*. When the lamp is lighted, the handle *g* is to be depressed: this causes the oil to escape through the hole *d* into the cistern *b*; and from this it runs by the side tube *i i* into the conical chamber *o*, which contains the wick *n*. This chamber consists of two tubes, *k k*, *l l*, one within the other, and joined at *m m*, so as to make a closed receptacle for the oil. In this receptacle the wick *n* plays freely up and down; and it is kept constantly immersed in oil, as high as the aperture *d*, in the cistern *b*. *p* is a cup placed at the bottom of the chamber to receive any oil that may run over from the wick. Atmospheric air rises freely through *c* into the centre of the flame, and it also blows upon the exterior of it: the cause of the current of air is the glass chimney which rests on the top of the burner.

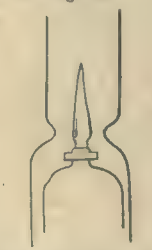

Fig. 101.

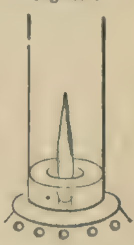

Fig. 102.

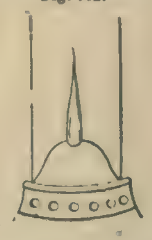

Fig. 103.

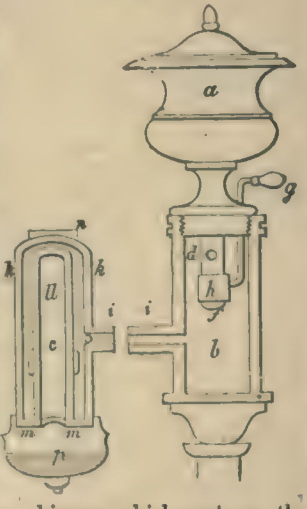
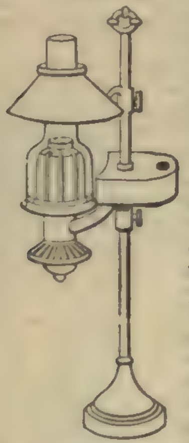


---

* See *ante*, p. 92.

Many forms have been given to this lamp of M. Argand, according to the purpose which it is intended to serve: thus, there is the reading or Cambridge lamp (Fig. 104), the well-known table lamp (Fig. 105), and the suspended lamp.

Fig. 104.



(*b.*) *The Rumford or Annular Table Lamp* is an improvement on the last. It was contrived by Count Rumford, for the purpose of avoiding the deep shadows which are produced by the reservoirs of the preceding; and it became so great a favourite, that even to this day it is occasionally used. The oil is contained in a hollow ring, which is placed a little below the level of the flame; and the cistern is fed by means of two tubes, which also serve as supports. In order to diffuse the light still more, the burner is surrounded by a ground-glass shade, which almost entirely conceals the ring (Fig. 106).

(*c.*) *Parker's Sinumbra Lamp* was patented in 1820. It was called the shadowless lamp, because it did away with the slight shadow which is always perceptible in the last. The improvement is threefold:—First, the annular reservoir is bevelled off from above, so as to present a very thin edge on the outside; secondly, the glass is shaped in such a manner as to diffuse the light over the edge of the ring, and under it; and, thirdly, a conical reflector is placed around the inner glass a little above the flame. All these arrangements are represented in Fig. 107, which shows the lamp in section.

Fig. 105.

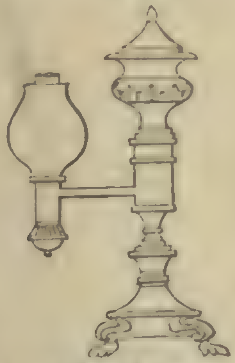


Fig. 106.

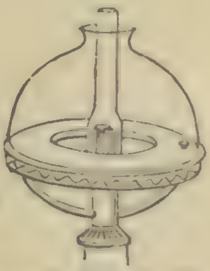

Fig. 107.

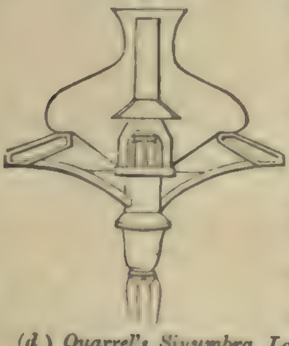
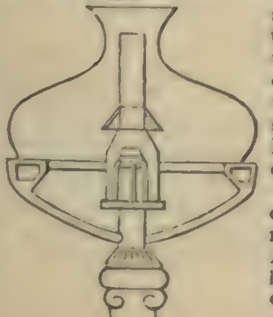


(*d.*) *Quarrel's Sinumbra Lamp* (Fig. 108) is another contrivance for effecting the same object as Parker's; but the bevelling of the reservoir is on the under surface of the ring, instead of the upper; and the ground-glass shade is made sufficiently large to reach to the very outer edge of the ring.

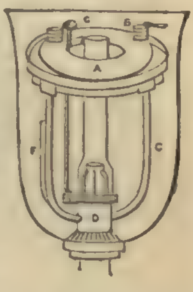
Fig. 108.



(*e.*) *The Iris Lamp* is one of the most recent improvements of the Rumford and Argand: it differs very little from the preceding, except that the outer edge of the annular chamber is reduced to a mere bead; and the ground-glass shade is not only brought to the very front of the ring, but its body is formed in such a way as to bulge over it. By these contrivances the shadow of the reservoir is reduced to a minimum.

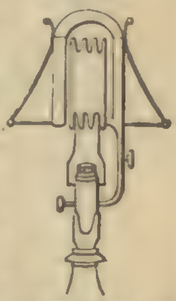
(*f.*) *Quarrel's Albion Lamp.*—This marks the next attempt to improve the Argand, by carrying the reservoir for the oil over the flame, and, therefore, out of the way of the shadow, instead of having it, as in Rumford's contrivance, around it and a little below it. The construction of this lamp is represented in Fig. 109. A is the reservoir for holding the oil, which is introduced through the two valve-cocks B; C is the tube that conducts it to the cistern D; and F is a syphon-valve for admitting atmospheric air to the reservoir, so as to supply the place of the consumed oil. G is a pinion for regulating the height of the wick. The whole is enclosed in a tulip-shaped glass; and, with the exception of the side-tubes, there is nothing to produce a shadow.

Fig. 109.



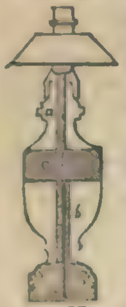
(*g.*) *Parker's Hot-oil Lamp* is constructed somewhat like the preceding, though a contrivance is adopted for making the oil hot before it reaches the wick; by which means it becomes more fluid, and burns with greater facility. Fig. 110 shows the plan of this lamp. The reservoir is above the flame, and the top of the glass is fitted into an iron chimney, which radiates heat very freely to the reservoir. The oil passes down through a lateral tube to the cistern, and there is a stopcock in the tube to cut off the supply of oil when necessary. The wicks are very short; and instead of being adjusted by the rack and pinion, a movement is given to the glass, which, by its position, regulates the intensity of the flame. A painted shade is put over the whole, in order that the reservoir may be hidden. The advantage of this lamp is, that it will consume the very commonest oil without producing an unpleasant smell. One caution, however, is necessary in the management of it—namely, that the reservoir be filled quite up with oil before the lamp is lighted. If this be not attended to, the air contained in the chamber will expand by the action of the heat, and the oil will be forced out over the wick, and will run about.

Fig. 110.



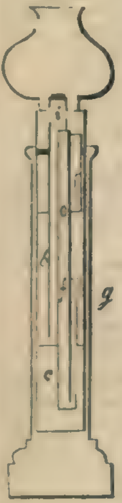
(*h.*) *Keir's Fountain Lamp.*—In all the preceding contrivances, the supply of oil to the flame is chiefly effected by the capillarity of the wick. In some cases it is assisted by the gravitation of the oil from a reservoir situated above the level of the burner. But it has always been thought desirable to have the reservoir in the stem or body of the lamp, so that the unsightly appearance of the chamber might be avoided, and the shadow which it invariably casts to a greater or less extent upon surrounding objects, entirely prevented. This, however, can only be accomplished by means of some power whereby the oil shall be pressed up from the well in which it is contained, to the level of the flame. "To effect this, two methods have been resorted to: one is on a hydrostatic principle, in the manner of Hiero's fountain, where the oil is placed in the body of the stem, and is raised to the wick, as it is wanted, by the pressure of a column of some fluid: in the other method, the oil is forced by clock-work mechanism, as in the lamp of Carcel of Paris. The first successful attempt of this kind in England, was in the lamp invented by Mr. Keir, about forty years ago, upon a hydrostatical principle; and although it is not used at present, being superseded by contrivances of a similar kind by other manufacturers, yet it will serve to illustrate the general nature of these lamps, of which several varieties have been brought partially into use."* Fig. 111 represents Keir's lamp, the vase and pedestal of which are hollow. *a* is a tube into which a certain quantity of salt and water, having three times the specific gravity of oil, is put. Upon this is poured the oil until the tube is full. The brine, or solution of salt in water, runs down into the pedestal of the lamp; and when the oil is poured upon it, the latter, by its weight, forces up the former through a second tube *b*, into a chamber *c*, in the upper part of the body of the lamp, and the oil takes the place of the brine in the pedestal. It will be noticed that the tube *a* reaches only to the top of the chamber in the pedestal, while the tube *b* passes down to the bottom of it. The brine is represented by diagonal lines, and the oil by dots. Now, in consequence of the great weight of the brine, as compared with that of the oil, the latter is forced up to the burner as fast as it is consumed; and thus, by a sort of natural spring, the flow of oil to the wick is constantly maintained. After a supply of salt and water has once been introduced into the lamp, there is no necessity for a further addition of it.

Fig. 111.



Similar lamps have been constructed on the same principle by King, Barber, and others; but they are all difficult to manage, and hence they are not much in vogue, although they generally have a very light and elegant appearance.

Fig. 112.

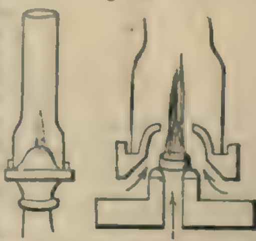


(*i.*) *Parker's Fountain Lamp* (Fig. 112) is a very complicated apparatus, which, like the fountain of Hiero, owes its action to compressed air. Externally it presents the appearance of a column surmounted by the lamp; but within this column there is another cylinder which contains the oil. This cylinder must be removed before the lamp can be charged. It is divided crosswise into three compartments, *a b c*, which have no direct communication with each other. Through the centre of the whole there passes a tube *f*, which is open at its top, and at the bottom it communicates by a sort of valve with the compartment *c*; it also communicates with the compartment *a*, by means of a hole which is seen near the top of the tube. The three compartments or chambers are therefore in indirect communication with each other; thus *a* communicates through the hole just mentioned with the tube *f*; this communicates by its bottom valve with compartment *c*; and this, by means of a tube and valve *g*, with the middle compartment *b*; and *b* communicates by means of an ascending tube with the burner *i*, in which the wick is placed: so that if oil be poured into the upper opening of the tube *f*, it will fill the compartment *c*; and then, on turning the apparatus upside-down, the oil will flow through *g* into the middle compartment *b*. On restoring the cylinder to its proper position, the oil cannot return to *c*, because of the peculiar form of the contrivance *g*—consequently it remains in the middle chamber; and now, on refilling *c* through the tube *f*, the air in the lowest chamber is compressed, and it forces the oil in *b* up through the lateral tube to the burner *i*. The chamber *a* is filled at the same time as *f*, and its contents flow as fast as they are wanted through the hole in the tube *f*, and thus keep up a supply to the pressure-column. Every time the lamp is charged it is inverted, in order that the oil in *c* may flow into *b*; and then it is returned to its original position, and recharged with oil. This lamp was reported on by the French Academy of Science, and it was formerly much used in India; though now it is superseded by the Iris lamp.

(*k.*) *The Carcel Lamp* presents much of the appearance of the last described; but instead of the flow of oil being effected by means of atmospheric elasticity, it is accomplished by the aid of machinery moved by clock-work. In this way the oil is raised, or rather pumped up, to the wick, so as to keep up a constant supply by continually overflowing it. The oil drips back into the cistern below; whence it is drawn up repeatedly, until it is all consumed.

(*l.*) *The Solar Lamp.*—This is Roberts's great improvement on the Argand, although it was patented by Mr. Bynner. It is a contrivance for increasing the supply of atmospheric air to the flame, and so enabling it to consume a larger proportion of oil, and thus to give out a greater body of light; besides which, it effects a more complete combustion of the oil, and therefore produces a more intense light. In all the common forms of Argand, the air passes straight up through the burner, and only slightly impinges on the two sides of the flame; but in this contrivance the current of air is broken, and made to blow in upon the flame. The apparatus which effects this is a small cone or nipple, that is dropped down over the flame (Fig. 113).

Fig. 113.



A still greater improvement on this principle is that of Quarrel, in which he causes a second current of air to enter under the glass, and thus to assist the other in blowing on the flame (Fig. 114); and by introducing a button into the centre of the flame (as was also originally proposed by Mr. Roberts), this inner current of atmospheric air is likewise deflected, and thus we get the greatest possible amount of oxydation (Fig. 115). By the adoption of such contrivances as these, almost any kind of oil, even the commonest fish-oil, may be burnt without producing any unpleasant smell.

Fig. 114.

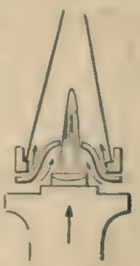


Fig. 115.

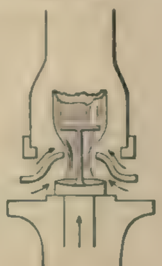

(*m.*) *The Bude Light* of Mr. Goldsworthy Gurney is only an extension of the preceding principle. Roberts increased the supply of atmospheric oxygen by means of the nipple, which others patented and applied to the solar lamp. Mr. Gurney, however, uses a jet of pure oxygen, or of an atmosphere rich in oxygen, which he throws into the centre of the flame by mechanical power; and by this means he increases combustion and light to an enormous extent. This light requires complicated apparatus for its production, and hence it has never come into general use.

(*n.*) *The Argand with Concentric Wicks.*—Many years since, Mr. Webster suggested that Argands might be made with two circular wicks, one within the other; and Sir Humphry Davy referred to the invention as one well adapted for obtaining heat for chemical purposes. A lamp on the same principle, with four concentric wicks, has since been constructed by M. Fresnel, for lighthouses; and, according to Dr. Brewster, it gives a light equal to forty common Argands; but the heat produced by the lamp is very intense.

5. *Lamps for Burning Solid Fats.*—The commonest form of these is the saucer and central-wick lamp, which may be seen so frequently in France during the nights of illumination; but a more agreeable form has been given to this kind of lamp by the Hon. G. Cochrane, who took out a patent for it a few years ago. His lamp is very much like an ordinary Argand, but it has a piece of metal over the flame which communicates with the chamber containing the fat, and thus keeps it warm and liquid (Fig. 116). The fats which are best suited for this lamp are cocoa-nut and palm; but tallow and kitchen-stuff may also be used.

6. *Camphine or Vesta Spirit Lamps.*—These are the

---

* Webster and Parker, p. 159.

names given to the lamps which are constructed to burn the highly rectified oil of turpentine—a liquid which Mr. English originally prepared and patented under the name of camphine. Mr. Young, of Queen-street, Cheapside, has devoted great attention to the manufacture of these lamps, which he calls *Vesta spirit lamps*. The reservoir for holding the camphine is made of glass, in order that the heat from the burner may not be communicated to it: in fact, every precaution is taken to guard against such a result; for the wick, instead of being supported on a long metal tube, which passes down into the body of the oil, as is the case with the common Argand lamps, is merely held at the top by a narrow ring, while the remaining portion floats freely in the spirit; besides which, the burner is insulated from the lamp by a collar of wood. The next point of importance in their construction is that which ensures an abundant supply of atmospheric air; for if this is not attended to, the turpentine burns with a remarkably sooty flame, and evolves a large quantity of black smoke. This is effected by having a slit in the side of the wick so as to allow the atmosphere to pass freely into its interior; and the nipple, or cap, of the solar lamp is used to break the outer current of air, and blow it into the flame; besides which, the chimney is very tall, and it is bulged in, or contracted, at the point where it reaches the flame. In the larger kinds of camphine lamps, the button of Mr. Roberts is also introduced into the interior of the flame, so as to break the inner current of atmospheric air (Fig. 117). And then, in addition to all this, a cylinder of perforated brass is put around the vent-holes of the burner, so as to prevent the ill effects of extreme draughts. The principles, therefore, which are kept in view in the construction of these, are—1st, to prevent the heating of the liquid; 2nd, to ensure a large supply of atmospheric air; and 3rd, to guard against the influence of external draughts. One of the great advantages of the Vesta lamp, is the intensity and purity of the flame. Dr. Ure says, that a lamp which consumes two ounces of camphine in an hour, gives the light of nearly twelve sperm or wax candles of three or four to the pound. Our own experiments show, that the smaller lamp, which has no button, consumes about 140 grains per hour, and gives the light of two-and-a-half sperm candles, each burning at the rate of 120 grains per hour; while the larger lamp, which has the button, consumes about 540 grains of camphine per hour, and gives the light of seven sperm candles.

Fig. 116.

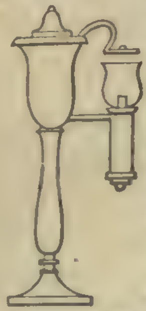

Fig. 117

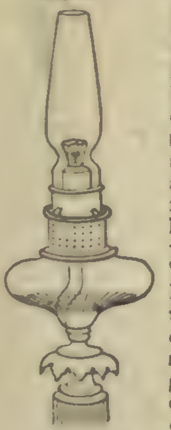
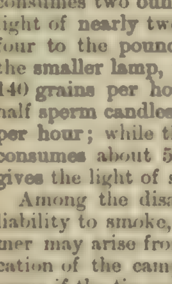


Among the disadvantages of the Vesta lamp, are its liability to smoke, and its disagreeable smell. The former may arise from bad management, or from a resinification of the camphine—a circumstance that is sure to occur if the tin-can containing the liquid is not kept well corked, or if too much liquid is put into the lamp for an evening's consumption.

Fig. 118.



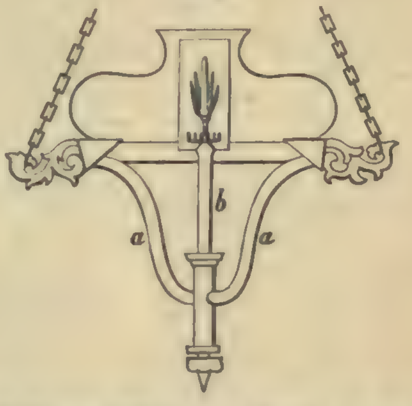
7. *Naphtha Lamps.*—Of these there are two kinds—viz., the Argand naphtha, which is constructed exactly like the preceding; and the flat-wicked lamp, which is represented in Fig. 118. In the latter, the air is directed upon the exterior of the flame by means of two lateral pieces of tin, which incline inwards as they ascend to the wick; and the supply of air is regulated by an external opening or valve, which may be shut up to any extent. When naphtha is burnt in a small Vesta lamp, it is consumed at the rate of about 136 grains per hour, and it gives the light of two standard sperm candles; when burnt in the large one, its consumption is 486 grains per hour, and its light is equal to nine sperm candles. The disadvantages of these lamps are, the unpleasant smell of the naphtha, the liability to smoke, and the danger of explosion; for naphtha, being much more volatile than camphine, is likely to give off vapour, which, with the air, forms an explosive mixture. Great caution is therefore necessary in managing these lamps.

8. *Gas or Vapour Lamps.*—Several attempts have been made at various times to burn inflammable liquids without a wick. The earliest and simplest of these is—

(*a.*) *The Common Floating Night-lamp*, which is nothing more than a small cup of metal pierced in the middle with a small glass tube. The oil rises by capillary attraction in the tube, and may be ignited.

(*b.*) Another form of *self-generating lamp* is represented in Fig. 119, where two tubes, *a a*, bring the oil down from the annular reservoir, and convey it into a cistern, whence it rises by the tube *b* into a cup which has a cylinder filled with it, pierced with a number of small holes that serve for jets. When the lamp is trimmed, alcohol is poured into the cup, and set fire to. This, in the act of burning, makes the cylinder so hot that the oil within it is converted into gas; and this escaping through the hole or jets, is fired, and burns with a brilliant light. The heat produced by the combustion of the gas, keeps up the supply. A glass is placed around the burner to protect it from external currents, and to prevent the flame from smoking.

Fig. 119.



(*c.*) A mixture of camphine or highly rectified spirits of turpentine with alcohol, is burnt on the continent in a lamp that was originally designed by Lüdersdorff, but which has been patented in France, by Ribot, under the name of "*Eclairage au Gaz Liquide.*" The French lamp is represented in Fig. 120. It is an elegant-looking arrangement, the body and stem of which are composed of cut glass. Fig. 121 exhibits the mechanism by which the spirit and turpentine are converted into vapour. *a* is the wick which floats in the liquid, and conveys it up through the tube *b* into *c*, which is the vapour chamber; *d* is a cap of brass, which, when heated

Fig. 120.

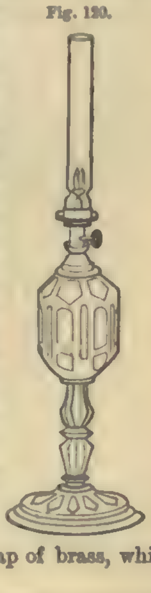


Fig. 121.

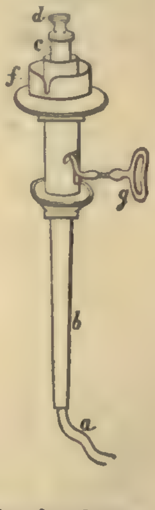

effects the vaporisation of the liquid, and causes the gas to escape through three little holes at its base; *f* is the collar for holding the glass; and *g* is a handle for turning the liquid off or on. When the lamp is to be lighted, it is filled up with mixed spirit; and the glass being removed, the handle *g* is to be turned from the left to the right. A ring of wire gauze, saturated with the spirit, is then lighted and brought down over the cap *d*, as low as *e*. This is to be kept burning until the metal cap and chamber are sufficiently heated to generate gas, which will escape through the holes and take fire. When this has occurred, the glass is to be replaced, and the burning jets will keep up the desired temperature. Instead of turpentine and alcohol, a mixture of equal parts of spirits of wine and coal-naphtha, or even coal-naphtha itself, may be used. The disadvantages of the lamp are its liability to go out with the least draught of air, and its danger of exploding.

(*d.*) *The Common Naphtha Lamp* is now extensively employed by poor tradespeople who keep their stalls out of doors. The construction of this lamp will be understood from Fig. 122: *a* is the reservoir for the naphtha, from the bottom of which there passes a tube *b*, which supplies the fluid to the burner *c*. A stopcock is inserted into the middle of the tube, in order that the supply of naphtha may be regulated, or even cut off altogether, when it is not wanted at the burner. Fig. 123 exhibits the construction of the latter: the naphtha enters by the tube *a*, and it flows out of a small hole which is in the lower arch of the burner, and trickles down into a small cup *b*; here it is lighted, and soon the combustion of the naphtha produces so much heat that it makes the whole body of the burner very hot. This causes the naphtha to assume the form of vapour or gas; and as it issues out of the small hole, it is forced up against the bottom of the disc *c*; and thence it comes spreading out in a star-like form all round the burner. This form is given to it by the little breaks of perpendicular wires which descend from the bottom of *c*; another small disc is placed below this to prevent the flame from bounding back upon the jet whence it issues from the tube; *d* is a small wire, which is withdrawn when the interior of the burner wants cleaning.

Fig. 122.

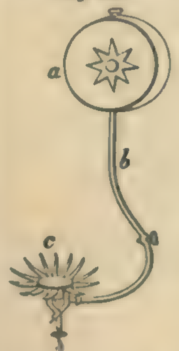

Fig. 123.

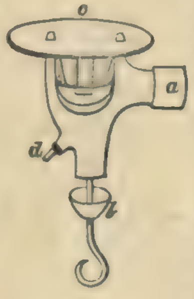
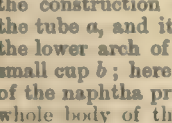


(*e.*) *Beale's Naphtha Lamp.*—This form of lamp was invented some years ago by Mr. Beale, of London: it consists of a vessel *a* (Fig. 124), in which the naphtha is placed; thence it flows by a lateral tube into the cup-shaped cistern *b*, and it is prevented from overflowing by reason of its being constructed in the same way as a bird-fountain. A tube *c* passes up through the bottom of the cistern, and reaches a little above the level of the liquid: this tube is placed in communication with a reservoir or gasometer containing air. Lastly, a brass cap *d*, having a hole in the top, is placed upon the cistern; the lamp is put into action by removing the cap and setting fire to the naphtha; air is then blown through the tube *c*, and the cap is gradually brought down into its place in the cistern, care being taken that it is sufficiently heated during its descent to keep up the volatilisation of the naphtha. When this is properly managed, the air which passes through the tube *c* carries with it so much naphtha vapour as to become inflammable, and burns with a brilliant jet of flame.

Fig. 124.



We have not thought it necessary to give a description of the different ornamental contrivances for setting up and supporting lamps, &c.—as, for example, candlesticks, candelabra, chandeliers, &c.; for this would entail a very elaborate account of the principles of ornamentation, which is not suited to the object of this work.

ON GAS.

General Remarks.—Long before gas was manufactured artificially, it was generated in the great laboratory of nature by the action of terrestrial heat on large accumulations of vegetable matter, as beds of coal. The products of this action made their way to the surface of the earth, and escaped in the form of gas and petroleum; both of which are highly inflammable. The fires thus generated, commanded attention at a very early period, and altars dedicated to the gods were erected over them. At the time that the Persians, under the command of Mardonius, overran Greece, there were innumerable altars lighted up in this manner; and so much were they reverenced by the Greeks, that when the Persians were defeated at the battle of Platæa, and driven from the country, the two victorious generals, Pausanias and Aristides, were directed by the Oracle of Delphi to build an altar to Jupiter, their deliverer, and not to offer any sacrifice upon it until they had extinguished all the fires throughout the country which had been polluted by the Persians, and had relighted them with the sacred fire from Delphi. In Plutarch's *Life of Alexander*, we are told, that when that monarch arrived at Ecbatana, "he was particularly struck with a gulf of fire, which streamed continually, as from an inexhaustible source. He admired also a stream of naphtha not far from the gulf, which flowed in such abundance that it formed a lake. The naphtha in many respects resembles bitumen, but it is much more inflammable; before any fire touches it, it catches light from a flame at some distance, and often kindles all the intermediate air. The barbarians, to show the king its force and the subtlety of its nature, scattered some drops of it in the street which led to his lodgings; and standing at one end, they applied their torches to some of the first drops, for it was night. The flame communicated itself swifter than thought, and the street was instantaneously all on fire."

For several thousand years the Chinese province of Se-tschuan has been celebrated for the quantity of inflammable gas that issues from the earth; and it has been stated, that the gas which escapes from the ground in the neighbourhood of Pekin, is collected by the inhabitants, and used for lighting the streets and houses. The holy fires of Baku, near the Caspian Sea, have a similar origin; and jets of inflammable air are evolved at Pietra Mala, not far from the road between Florence and Bologna; at Maina, which is a few miles from Modena; at Lycia, in Asia Minor; and at the Artesian wells of Lichweg, in Schauenburg. In this country the gas is abundantly produced from the fissures of coal mines, where it is known by the name of *fire-damp;* and it is also evolved from stagnant pools, when it is termed *marsh gas.* At the village of Wigmore in Herefordshire, inflammable gas has on several occasions escaped from the earth to such an extent, that it has been made the means of lighting the neighbourhood. The same has been the case at Charlemont in Staffordshire, and at a place near Glasgow. Not long since, a considerable jet of gas was discharged from the Chat Moss, near to the Manchester and Liverpool Railway, and it was used by a neighbouring farmer for the purpose of working a small steam-engine. In the village of Fredonia, in the state of New York, the gas issues from the earth in such abundance, that the inhabitants collect it, and employ it for lighting the streets.

History of Gas Lighting.—It would naturally be supposed that facts like the preceding would, at a very early period, have commanded the attention of practical men of science, and that some effort would have been made to imitate the process which they saw going on in nature. Some, indeed, have thought that the ancient

Greeks were really acquainted with a mode of generating gas, and that the chief priests took advantage of such knowledge in exciting the veneration of the people. The altar in the temple of Ægina is described by Dr. Dodwell as having a round hole, thirteen inches in diameter, cut out of the top of it. This hole communicates with another which passes down through the solid stone to the depth of several feet, and there it opens into a cavity which is supposed to have contained fire that was always burning. He says that nothing more was necessary than to pour oil into the upper opening; and as it trickled down, it would be converted into gas, which would burst forth as flame, and appear to have a miraculous origin. But however possible, or even probable, the truth of this supposition may appear to be, it is certain that nothing practical was undertaken in Europe until the beginning of the 17th century, when Van Helmont, the physician and alchymist of Vilvorden, was led, in the course of his investigations, to expose a quantity of animal and vegetable matter to the action of heat in a closed vessel. By these means he obtained a "vapour," or "spirit," that burnt with a bright flame; but he little imagined that this *gaz fuliginosum*, as he termed the vapour, would one day become an agent of general illumination. Nor even at a much later period—namely, in the year 1726—when Dr. Hales informed the chemists of his time, that by distilling a few grains of Newcastle coal, he had obtained an equal number of cubic inches of inflammable air, could it be supposed that a similar experiment, on a very gigantic scale, would be daily performed in every city in Europe, and that millions of cubic feet of that subtle, inflammable material would be made to traverse, unseen, along the highways of the land, and be the means of lighting them up into an almost perpetual day.

Again, we may take up the history of our subject from another important discovery. Some time before the death of the Honourable Robert Boyle (1691), a letter was written to him by the Rev. Dr. Clayton, on the subject of distilling pit-coal. That letter was published many years afterwards—in 1739—in the Transactions of the Royal Society; and the author states, that from an examination of some inflammable vapours which were given off from a ditch near Wigan in Lancashire—vapours which had been collected and examined by Thomas Shirley in 1659—he was led to conclude that they came from the coal of the neighbourhood, which was acted on by terrestrial heat. Accordingly, he obtained a portion of the coal, and distilled it in a retort over an open fire. By this means he obtained a "phlegm," which first passed over; then a "black ore;" and lastly a "spirit," which he could nowise condense, for it forced the luting of his apparatus, and broke his glasses. This "spirit" was coal gas; and on discovering its inflammable nature, he was in the habit of collecting it in bladders and oiled silk bags, and thus preserving it for the amusement of his friends.

As yet, however, he had not learnt to burn it from a metallic jet, for he was accustomed to prick a hole in the bag, and then to set fire to the gas as it issued forth. For a period of more than fifty years these interesting facts were allowed to slumber, and no one entertained the idea of applying them to any useful purpose. At length, in the year 1792, just one hundred years after Boyle's death, an ingenious engineer and miner of Cornwall, whose name was Murdoch, conceived the notion that gas might be conveyed through pipes to a distance, and be thus employed as an illuminating agent. Acting upon this idea, it was not long before he had the satisfaction of seeing his house and offices at Redruth lighted up with Dr. Clayton's "subtle spirit." He also collected the gas in bladders, and used it as a means of lighting himself along the road between the mines and his own house; for which piece of ingenuity he acquired the reputation of a wizard. Soon after this, Mr. Murdoch was employed in the establishment of the celebrated engineers, Messrs. Bolton and Watt. There he erected apparatus for the manufacture of gas; and at the peace of Amiens, in 1802, he lighted up their factory for the first time with this agent. About a year afterwards, gas was generally employed in all the workshops of the factory; and in 1804 he set up a similar apparatus in several of the large cotton-mills of Lancashire—one of the earliest of which was the establishment of Messrs. Phillips and Lee at Manchester.

Ten years after this—in 1813—the manufacture of gas had extended to London, and in that year Westminster-bridge was lighted with it. Mr. Clegg gives an account of the horrors of the lamplighters when they first beheld the burning gas, and how he was obliged to light the lamps himself for some time, on account of the fears of the people. Even such men as Sir Humphry Davy and Sir Joseph Banks were unable, for many years after this, to overcome the prejudices which existed in their minds concerning it; and they thought the scheme a wild and dangerous one. The public, however, soon became reconciled to it; and in 1814 the oil-lamps were removed from the streets of St. Margaret, Westminster, and gas-lights were put into their places. This was the first parish that entered into a contract to have the streets lighted with gas.

In the same year the allied sovereigns came to this country; and as they were to be fêted and feasted in no ordinary manner, a great opportunity occurred for the use of gas, where no other means of illumination could be employed. On the ornamental water of St. James's Park a magnificent pagoda was erected; it was furnished with thousands of jets of gas; and in an instant, as if by magic, they all burst forth into flame, and gave the building the aspect of a brilliant fountain of fire. At one of the City feasts, the Guildhall was lighted up in a similar manner; and we are told by one of the journals of the time, that the light was "clear as summer's noon, but soft and undazzling as moonlight, forming a magnificent combination worthy the inauguration of the presiding citizen of the great city." Up to that time the gas was marvellously impure, and its fœtid odour proved an insurmountable barrier to its use in private houses. Eventually the attention of chemists began to be directed to this point; and as the processes of manufacture and purification were perfected, the use of gas became more general; so that in 1822 there were four great companies established in London, having forty-seven gasometers, supplied by 1,315 retorts, which generated upwards of 397,000,000 cubic feet of gas annually, supplying about 61,000 private lamps, and 7,268 public ones. In five years this quantity had nearly doubled itself; and in ten years more it was doubled again; so that in the year 1837 it had acquired so much importance as to become a subject for parliamentary investigation. In that year a paper was laid before a committee of the House of Commons, by Mr. Hedley; from which we gather, that for lighting London and its suburbs, a capital of £2,800,000 was employed. This yielded a revenue of £450,000, and furnished an annual supply of 1,460,000,000 cubic feet of gas. Twelve years after this, we are told by Mr. Croll, in his evidence before the committee of the House of Commons on the Great Central Bill, that the consumption of gas in the metropolis, during the year 1849, was more than double that of the preceding estimate; for it amounted to 3,200,000,000 cubic feet annually, of which the City alone consumed 500,000,000. This was distributed to 2,678 public lights, and to a multitude of private consumers. The area of the metropolis is about sixty-six square miles, and that of the City, one mile. In the former space there are, according to Mr. Barlow, about 2,400 miles of main-pipes, which run along 1,500 miles of streets; and in the latter there are about 110 miles of main-pipes, which light up 75 miles of streets. The surveyor to the Corporation states, in one of his reports, that the length of the public way in the City is only 51 miles, and that the lamps average 54 to each linear mile, or 1 in every 33 yards. But perhaps the best estimate of the enormous extent to which this branch of industry is carried on, may be formed from a statement made by Dr. Hoffman, on the authority of Mr. Lowe, who is one of the oldest gas engineers of the present time. He says, that about 6,000,000 tons of coal are annually consumed in England in the manufacture of gas; and as each ton of coal, on the average, produces about 10,000 cubic feet of gas, we have the almost incredible quantity of 60,000,000,000 cubic feet of gas produced yearly.

Action of Heat on Organic Matter.—As a preliminary to the study of gas-making, it is necessary that something should be known of the changes which occur when animal or vegetable matter is subjected to the action of heat. Chemists have shown that the effects vary with the temperature. At first, when the heat is not considerable, the matters evolved consist of aqueous vapour, organic acids, ammonia, and various combustible fluids which are soluble in water. In the second period, when the heat is somewhat higher, the products are carbonic acid, carbonic oxide, water, and a number of oleaginous or empyreumatic compounds, which are not soluble in water; and lastly, when the temperature is still higher, the products of the decomposition are hydrogen, marsh gas, and sundry hydro-carbons, which retain their gaseous condition. In the case of non-nitrogenous bodies, as wood, resin, fat, oil, &c., the chief products of distillation are water, acetic acid, naphtha or wood-spirit, volatile oil, tar, paraffine, creosote, carbonic acid, carbonic oxide, olefiant gas, super-olefiant gas, marsh gas, hydrogen, &c.; and when the substance contains nitrogen and sulphur, as is the case with coal, there are evolved ammonia, aniline, leukol, picoline, lutidine, &c., together with cyanogen, sulpho-cyanogen, and most of the compounds just named. In every case there remains in the retort a quantity of carbonaceous matter, which goes by the name of coke.

Of the gases which are thus evolved, the most important are hydrogen, carbonic oxide, marsh gas, olefiant gas, and various hydro-carbons which give to gas its high illuminating power: all the others are positively injurious, and ought, therefore, to be got rid of before the gas is supplied to the public. An examination of the quality of these gases will readily convince us that they may be divided into three kinds—namely, the light-giving gases, the diluters, and the positive impurities. Of the *light-giving gases*, the following are the most important:—

(*a.*) *Olefiant gas* (C^4H^4): a compound that was discovered in the year 1795, by the associated Dutch chemists, and was so named from the property which it has of forming an oily-looking fluid when it combines with chlorine. It is an odourless gas, and has a specific gravity of 0·97. It burns with a bright yellow flame, and consumes three times its bulk of oxygen, or nearly fifteen times its bulk of atmospheric air, producing twice its volume of carbonic acid. The gas is readily condensed by chlorine, bromine, and anhydrous sulphuric acid; it is also absorbed to a slight extent by water.

(*b.*) *Other hydro-carbons*, as *Propylene* (C^6H^6), or the super-olefiant gas of Dalton and Henry, *Etherene* (C^8H^8), or the volatile gas of Faraday, and perhaps some others of a like atomic composition, are met with in most of the illuminating gases of commerce. These, like the last, consist of equal proportions of carbon and hydrogen. They are very condensible by chlorine, bromine, and anhydrous sulphuric acid, and they burn with a very bright sooty flame.

The *diluting gases* are marsh gas, hydrogen, and carbonic oxide. These are important constituents of common gas, because they serve as the purveyors of the rich illuminating hydro-carbons, which could not be burnt alone.

(*a.*) *Marsh gas, or light carburetted hydrogen*, is a compound of one atom of carbon and two of hydrogen (CH^2). It is about half as heavy as atmospheric air, and it burns with a bluish flame, tipped with yellow. It consumes twice its bulk of oxygen, or nearly ten times its bulk of air; and it produces its own volume of carbonic acid.

(*b.*) *Hydrogen* is the lightest of all known substances. It weighs but a fifteenth of its bulk of atmospheric air. It burns with a pale blue flame, and consumes only half its bulk of oxygen, or two-and-a-half times its bulk of air; the sole product of its combustion being aqueous vapour.

(*c.*) *Carbonic oxide* (CO) is a little lighter than atmospheric air. It burns like the preceding, with a blue flame, and consumes only half its volume of oxygen. The product of its combustion is its own bulk of carbonic acid.

The *impurities of gas* are carbonic acid, ammonia, sulphuretted hydrogen, bisulphuret of carbon, tarry matter, and various compounds of cyanogen and sulphur.

(*a.*) *Carbonic acid* (CO^2) is a very heavy gas—its density being about 1·5. It is not only incombustible, but has the power of checking the combustion of all inflammable gases. It is freely absorbed by lime and alkalies. Water takes up about its own bulk of the gas.

(*b.*) *Ammoniacal gas* (NH^3) is about half as heavy as atmospheric air. It is not combustible, unless it is decomposed by the heat of some other burning body; and then the hydrogen of the gas burns in the usual manner. Ammonia is readily absorbed by water, and by solutions of acids and metallic salts. It is known by its communicating a red colour to turmeric paper, and by fuming with muriatic acid.

(*c.*) *Sulphuretted hydrogen* (HS) is a most unpleasant-smelling compound; it is a little heavier than atmospheric air, and burns with a pale-blue flame that evolves the odour of a burning match. When plenty of atmospheric air is present, the products of its combustion are water and sulphurous acid; but if the supply is limited, water alone is formed, and the sulphur is precipitated. The sulphurous acid, when produced, quickly absorbs more oxygen, and becomes sulphuric acid—a compound that exerts a most destructive influence on every kind of textile fabric. When sulphuretted hydrogen escapes into the air without burning, it discolours lead paint, and tarnishes silver. On these accounts, sulphuretted hydrogen is regarded as one of the most injurious compounds of ordinary gas. It is absorbed by lime, and by the salts of iron, zinc, copper, and lead; and the test for it is a piece of white paper dipped in a solution of sugar of lead.

On exposing such paper, while damp, to the action of the gas, the lead-salt is quickly discoloured; and thus the smallest trace of sulphuretted hydrogen may be easily recognised.

(*d.*) *Bisulphuret of carbon* (CS^2) is even a more serious impurity than the last, for it not only produces the same acid compound by its combustion, but is also more difficult of detection; and then, again, chemists are not yet acquainted with any process for the removal of this noxious body from the gas of commerce. All these circumstances give it an importance that it would not otherwise possess. Bisulphuret of carbon, when pure, is an oily-looking liquid, that sinks in water. It evolves the unpleasant odour of putrid cabbage, and boils at a temperature of 106° Fah.; it burns with a blue flame, and its vapour consumes twice-and-a-half its bulk of oxygen, or nearly twelve-and-a-half times its bulk of atmospheric air, producing twice its volume of sulphurous acid, and half its volume of carbonic acid. This compound is best recognised by burning the gas, and collecting the products, in which sulphurous or sulphuric acid will be discovered.

(*e.*) The *tarry matters of inflammable gas* are of a very complex nature; they appear to be held in solution by ammonia, and to be precipitated in the form of dark flakes, when the gas is made to pass through a vessel containing flints moistened with acid. It is very probable that these tarry matters are of an acid nature, and that, in their union with ammonia, they produce compounds that are sufficiently volatile to be suspended in the gas.

(*f.*) The *cyanogen compounds* are not likely to be found in the gas of commerce, for they are readily absorbed by the lime made use of in its purification. Of these, cyanogen, hydrocyanic acid, and sulpho-cyanogen are the most important.

The Manufacture of Gas.—In all cases, the destructive distillation of the organic substance which yields the gas is effected in a vessel called a retort, which is set in a furnace; and the gaseous products are purified by transmitting them through a series of vessels named condensers and purifiers. The details of the process vary with each particular gas, and, consequently, it is necessary to describe them under different heads.

Coal Gas.—The *apparatus* which is employed for the manufacture of coal gas consists, first, of a *retort*, made of iron or clay, set in a furnace in such a manner that it may be heated throughout to a tolerably uniform temperature; an *outlet pipe* ascends from the end of the retort, and terminates in another pipe, called the *hydraulic main*. This part of the apparatus is so constructed, that the pipe which delivers the gas from the retort dips down, to the extent of three or four inches, into the liquid contained in the hydraulic main. By this means the end of it is sealed or closed by a water-valve, and no gas can return from the other parts of the apparatus into the retort during the time that the latter is being charged with coal. The *hydraulic main* is a large horizontal pipe, which runs from one end of the building to the other; it receives all the exit-pipes from the retort, and discharges its contents into a series of smaller pipes, which are so arranged in water and air, as to form a large cooling surface for the condensation of the liquid matters contained in the raw gas. Here it is that water and tar are deposited; and the apparatus is so constructed that the fluid matters run off, as fast as they are condensed, into a tank which is conveniently placed to receive them. This part of the apparatus is called the *condenser*. From the condenser the gas passes to the *purifiers*, which are vessels charged with lime and other substances that have the power of absorbing the various impurities of coal gas. To assist the flow of gas through these vessels, an instrument called *an exhauster* is sometimes employed: it is a kind of air-pump worked by a steam-engine, which draws the gas away from the retorts, and so relieves them from that enormous amount of pressure that they would otherwise have to encounter while their gaseous contents are being forced on through the various obstructions that intervene between them and the gasometer. Leaving the purifiers, the gas passes into the large receiver or gasometer, where it is stored.

Materials employed in the Manufacture of Coal Gas.—Of the three varieties of coal, known to chemists, the black or bituminous is the only one which is employed to any extent for the manufacture of gas. Lignite, or brown coal, is not sufficiently plentiful for this purpose; and glance-coal, or anthracite, is not rich enough in hydrogen to be of any use to the gas manufacturer. A small quantity of a peculiar bituminous shale, named Boghead coal, has of late been employed in London and elsewhere; but its nature is not sufficiently well determined to enable us to say whether it is to be regarded as a coal or not.*

The varieties of black coal are exceedingly numerous: in a general way, however, they may be divided into four kinds—namely, caking coal, which has the property of melting when it is heated, and of running together; splint coal, which is so named from its splintery fracture; cherry coal, which burns without caking at all; and cannel coal, which is exceedingly hard, compact, and bituminous. The first of these occurs abundantly in the neighbourhood of Newcastle, Northumberland, and Durham; the second in South Wales; and the last in Scotland and in Lancashire. Although these varieties of coal differ very considerably in their value for gas-producing purposes, yet regard must always be paid to the convenience or facility with which they are obtained; and hence we find that, in London, the coals of Newcastle, with certain cannels of Lancashire and Scotland, are employed. In Bristol and its neighbourhood, the coals of Gloucestershire and Wales are used; in Birmingham, those of Staffordshire and Wigan; in Leicester, Nottingham, and Derby, the coals of Derbyshire; in Leeds and Sheffield, those of Yorkshire; in Liverpool, Salford, and Manchester, those of Wigan; in Edinburgh and the north of Scotland, the coals are chiefly derived from the Lothians and from Fifeshire; in Glasgow they are obtained from Lesmahago, Kelvinside, Wilsontown, &c.; and in Greenock they are procured from Monkland and Skaterig.

The temperature at which the carbonisation of the coal is effected, and the manner in which the heat is applied, have an important influence on the quality of the gas and other products obtained. If the heat is too low, the quantity of gas produced is small, while that of the tar is large: on the contrary, if it is too high, the latter is sacrificed for the generation of the former. In the one case the gas is too rich in hydro-carbons, and in the other it is too poor. In practice, therefore, it is necessary to hit the happy medium; and it is generally thought that Newcastle coal requires a temperature of a dull red heat (1300° Fah.) for its distillation, and that the richer cannels will bear a temperature of 1800° Fah., or a bright cherry red.

Some idea may be formed of the relative value of the different kinds of coal, by reference to the following table, which exhibits the proportions of volatile matter, coke, and ash, produced by each description of coal, as well as the per-centage of sulphur contained in the coal, the coke, and the gas. The coals are arranged in the order of their gas-producing properties; and it will be seen that the amount of volatile matter ranges between 23 and 68 per cent., and that the quantity of sulphur contained in the volatile matter is from 1 to 5 per cent.:—

With regard to the manner in which heat is to be applied, it may be said, that, within certain limits, the more quickly it is so, the greater the quantity, and the better the quality of the gas obtained; for too slow a heat generates volatile matter, which condenses in tar; and too quick a heat decomposes the gas, and destroys its illuminating powers. Lastly, it may be remarked, that the duration of the heat ought not to exceed five hours; for at the expiration of that time the gases which are evolved are of little use for illuminating purposes, and the sulphur which is contained in the coke begins to distil over as bisulphuret of carbon, which is a most objectionable impurity.

Purification of Gas.—This is effected in various ways; some of the contrivances being mechanical in their action, and others chemical. When the volatile matters quit the retort, they consist of aqueous vapour, tar, olefiant gas, and other rich hydro-carbons, light carburetted hydrogen, hydrogen, carbonic acid, carbonic oxide, sulphuretted hydrogen, sulphuret of carbon, cyanogen, and ammonia. Only a few of these are required for illuminating purposes, and the rest must be got rid of. Foremost in the order of purification is that which takes place in the hydraulic main. There the most condensible of the empyreumatic vapours are deposited, and they run away into the neighbouring tank as a most fœtid mixture of tar and watery matters. Next to this is the condenser—an apparatus which exposes the gas to a large extent of cooling surface. We have already described the form of the apparatus, and said that it causes the condensation of the liquifiable matters contained in the gas. It precipitates tar, water, and ammonia, in combination with sulphuretted hydrogen, carbonic acid, and cyanogen. In some cases, the gas is made to pass through a vessel containing pieces of coke, over which a stream of water is constantly running. The gas enters at the bottom of the vessel, and, having made its way between the fissures of the coke, it escapes at the top. A stream of water runs over the coke in an opposite direction; and thus the gas is, as it were, washed and scrubbed by the two materials with which it is brought into contact. This apparatus is, therefore, very appropriately named a *scrubber*. The only impurities then left in the gas are ammonia, carbonic acid, sulphuretted hydrogen, cyanogen, and bisulphuret of carbon. These can only be removed by the aid of chemical absorbents; and the gas is, therefore, made to pass through a set of vessels which are named *par excellence*, the purifiers. These contain milk of lime, or lime that has been recently slaked. In the former case it is named a wet-lime purifier, and in the latter a dry. In both cases the gas enters at the bottom of the vessel, and it is either distributed in a stream of small bubbles through the liquid, or else it pursues its way between the moist particles of the recently slaked lime. By this contrivance, carbonic acid, cyanogen, and sulphuretted hydrogen are extracted from the gas; these combine with the lime, and produce a most unpleasant-smelling compound, which is technically termed *blue-billy*. In consequence of the loss of ammonia by this process of purifying, and the disgusting nature of the refuse materials, a number of patents have been taken out at various times for the purification of coal gas by other means than that of lime alone. The oxides of iron, in various conditions, have been patented by Messrs. Croll, Hills, Laming, and Lowe; the common salts of lead have been patented by Mr. Lowe and Mr. Losh; oxy-chloride of antimony, by Mr. Kirkham; sulphate of iron, with common salt and charcoal, by Mr. Cormack; sulphate of lime and magnesia, by Mr. Hills; superphosphate of lime, by Mr. Johnson; muriate of lime, by Mr. Laming; muriate of manganese, by Mr. Croll; and clay, by Mr. Bowditch.[*] Indeed, it would appear as if all the refuse matters of the arts had been successively tried and patented, in the hope of their becoming a means of extracting the impurities from coal gas. In most cases these substances merely absorb ammonia, and in a few instances they take up sulphuretted hydrogen also. Quitting the purifiers, which are charged with one or more of the preceding compounds, the gas enters the gasometer, and is in the condition in which it is to be supplied to the public.

---

* At the present time (July, 1861), an action is pending in the Scotch law courts to decide this question, between the lessors and lessees of the Torbanehill property.—*Editor.*

The products of these operations are more or less valuable in every stage of the process. The coke which is drawn from the retort after the extraction of the gas, meets with a ready sale; the ammoniacal liquor which floats upon the tar in the tanks of the condenser and hydraulic main, contains enough ammonia to make about sixteen ounces of sulphate, twelve-and-a-half of carbonate, or eleven-and-a-half of muriate, from each imperial gallon; and as each ton of Newcastle coals produces from ten to twelve gallons of this liquor, there is a large amount of valuable matter generated in the process. The tar also is made to give up its wealth by the all-powerful aid of chemistry. As it leaves the manufactory, it is a dark-coloured, heavy liquid, of a most unpleasant odour: but, by distillation in rude iron boilers, it furnishes naphtha for lamps, dead-oil or creosote for railway timbers, and pitch or asphaltum for a variety of purposes. When the richer varieties of cannel coal have been used for the generation of gas, the tar also contains paraffine, which has already been described; and it likewise yields, by distillation, an oil which is largely employed for lubricating machinery. Within the last few years a number of patents have been taken out for the management of coal-tar; but as yet we have only begun to have an insight into the nature of the many valuable compounds that are locked up in it. Nevertheless, three classes of bodies have already been discovered in coal-tar; namely, neutral principles, acid substances, and alkaline matters. Among the first are benzole ($C^{12}H^{6}$), toluole ($C^{14}H^{8}$), cumole ($C^{18}H^{12}$), cymole ($C^{20}H^{14}$), naphthaline ($C^{20}H^{8}$), paranaphthaline ($C^{30}H^{12}$), pyrene ($C^{15}H^{4}$), chrysene ($C^{12}H^{6}$), paraffine ($C^{20}H^{21}$), and various liquid hydro-carbons, which nave not yet been isolated Among the acid substances, the most important is the acid of creosote, or carbolic acid ($C^{12}H^{6}O^{2}$); and of the alkaline matters there are pyridine ($C^{10}H^{5}N$), pycoline ($C^{12}H^{7}N$), and its homologue, aniline ($C^{12}H^{7}N$), lutidine ($C^{14}H^{9}N$), leucoline ($C^{18}H^{7}N$), a new base ($C^{16}H^{11}N$), and parvoline ($C^{18}H^{13}N$): in addition to which, there are, in all probability, other compounds which are isomeric with the preceding. Now the great and interesting fact which has been developed by the study of these compounds is, that they all contain but one element of nitrogen, and that, with one or two exceptions, they rise by regular gradations of two of carbon and two of hydrogen: first we have $10 + 5$, then $12 + 7$, then $14 + 9$, and so on. Besides which they are all isomeric, or have exactly the same composition with another series of bases called the aniline series. To the chemist these facts are of the greatest importance, not merely because of their individual interest, but because of their influence on the doctrines of science. At one time it was thought that whenever two things differed in their chemical and physical properties, they must be different also in their composition; and when Professor Faraday showed that one of the constituents of the fluid obtained by the condensation of oil gas, was identical, in its chemical composition, with another body (olefiant gas), notwithstanding that it differed from it in all its physical properties, chemists were hardly able to comprehend it; but ere long the fact was recognised as one of the most common occurrences in the whole range of chemistry. And thus an examination of the most insignificant of materials, will often furnish results that not only affect the ancient land-marks of science, but also open up a new way to the practice of industry and the acquirement of wealth. Who, for example, could have supposed that so disgusting a liquid as coal-tar—a liquid which, a few years since, the manufacturers of gas knew not how to dispose of—would, through the golden key of chemistry, be made the means of changing the aspect of chemical science, and of opening up new and profitable branches of industry? Take the crude tar, and submit it to distillation at a low temperature—the temperature of boiling-water: it yields a light volatile oil, which is commonly called naphtha. This consists, in great part, of a valuable ethereal liquid, which we have already described under the name of benzole—a liquid which may be used for burning in lamps, for dissolving resins, and for manufacturing a rich perfume (nitro-benzole), which has the delicious odour of the essential oil of bitter almonds. By continuing the distillation at a somewhat higher temperature, there passes over an oil which is heavier than water. This is called dead-oil; it contains the naphthaline, paraffine, creosote, and various liquid hydro-carbons, which have not been sufficiently well studied, but which perhaps contain mines of chemical wealth. The dead-oil is largely employed for the preservation of timber, and for lubricating machinery: and lastly, that which remains in the still is asphalt or pitch. As might be expected, there is a difference in the quality of these products, according as the tar is obtained from common Newcastle coal, or from the richer sorts of cannel.*

---

[*] Mr. Leslie employs sulphate of copper and acetate of lead for such purposes, in his purifiers at the houses of the consumers.—*Editor.*

Of the other impurities or products of gas-making, cyanogen is the most important; already it has been extracted from the impure gas, and converted into Prussian blue. It is said that a ton of Newcastle coal will yield enough cyanogen to produce seven pounds of Prussian blue—a quantity that will, at the present market-price of the pigment, almost cover the original cost of the coal.

The mode of obtaining this compound is very simple. When the raw or impure gas is purified by hydrated oxide of iron, according to the patents of Croll, Laming, and Hills, the cyanogen combines with the iron, and produces the pigment in question. But when thus made it is largely contaminated with sulphuret of iron and other impurities. These may be got rid of by washing the mixture with dilute sulphuric or muriatic acid. Or if the iron compound is treated with a solution of potash, it gives up its ferro-cyanogen, and produces prussiate of potash, which is an equally valuable compound.

The following table, which has been constructed from the experiments of Messrs. Barlow and Wright, will afford some idea of the relative proportions of gas, tar, ammoniacal liquor, and coke, furnished, per ton, by different varieties of coal:—

Coal.	Gas in cubic feet.	Tar in lbs.	Ammo. liquor in lbs.	Coke in lbs.
Pelton main	9650	102	102	1,543
Newcastle cannel	9630	98	60	1,426
Wigan (Ince Hall) . . .	10850	248	162	1,332
Lochgelly cannel	8381	225	340	1,245
Boghead	13340	733	0	715
Lesmahago	10779	506	41	1,077
Ramsay cannel	9016	295	61	1,435
Derbyshire deep main . .	9400	219	179	1,335
Wemyss	10564	210	very little	1,156

Tests for the Impurities in Coal Gas.—Notwithstanding that so much trouble is taken with the purification of coal gas, yet it is found that a greater or less proportion of the several noxious compounds already described, will escape absorption, and will find their way into the street mains. The most important of these are ammonia, carbonic acid, sulphuretted hydrogen, bisulphuret of carbon, and tarry matter.

The first of these is objectionable from the circumstance that it attacks the fittings, corrodes the meters, and fixes the stopcocks; besides which, it has the property of holding tar in suspension. Ammonia ought not to exist in coal gas to a greater extent than one part in about 50,000: that is, 100 cubic feet of gas ought not to contain more than about 3·5 cubic inches, or rather more than half a grain, of ammoniacal vapour. Anything approaching to this quantity may be readily discovered by means of turmeric paper, which is immediately reddened by the impure gas.

The presence of carbonic acid may be known by collecting a bottleful of the gas, and shaking it up with a little lime-water; if the impurity be present, the lime-water will be rendered milky. The great objection to carbonic acid is, that it reduces the illuminating power of the gas, and thus lowers its value. Mr. Wright and Mr. Lewis Thompson say, that every one part of carbonic acid in a hundred of gas, reduces its illuminating power to the extent of eight or ten per cent.

Sulphuretted hydrogen may be discovered by a solution of sugar of lead, a little of which ought to be dropped on a strip of white paper, and then held in the gas for a period of not less than ten minutes or a quarter of an hour. If the paper becomes discoloured, sulphuretted hydrogen is present. There are several reasons why this impurity should not exist in coal gas: it gives to the gas a fœtid odour; it tarnishes silver, and destroys the beauty of paint; and in the act of burning, it generates sulphuric acid, which acts injuriously on books, linen goods, and other textile fabrics.

Bisulphuret of carbon is not so easily detected, for the gas must be burnt under a platinum rosette, and the products of combustion collected in a vessel containing a little ammonia. Mr. Wright, of the Western Gas Company, has contrived an apparatus for this purpose. Having consumed about twelve cubic feet of gas, at the rate of half a cubic foot per hour, it will be found that six or seven ounces of water will have condensed in the receiver. This is to be treated with a solution of nitrate of baryta, that has been rendered acid by a little nitric acid. If, in the course of a few hours, a white powder settles to the bottom of the liquid, then bisulphuret of carbon was present in the gas; and if the precipitate is collected and weighed, the quantity of impurity present can be determined; for every 234 grains of sulphate of baryta represent 38 grains, or nearly 46 cubic inches, of the vapour of bisulphuret of carbon. By proceeding in this way, it will be found, that 100 cubic feet of coal gas yield from 50 to 300 grains of sulphate of baryta—quantities that represent from 8·1 to 48·6 grains of bisulphuret of carbon. The presence of this impurity in coal gas is a most serious affair: for it has been shown by Dr. Letheby, in several of his reports to the Corporation of London, that bisulphuret of carbon, in the act of burning and oxydising, forms sulphuric acid; a great portion of which escapes in a corrosive form, and does enormous damage to every kind of textile fabric. He states, that the books in almost every library in the kingdom where gas is used, are falling to pieces from the action of this acid upon the covers; and he makes reference to the libraries of the Athenæum Club-house, the London Institution, the Royal College of Surgeons, the Portico Library at Manchester, and that of the Literary Society at Newcastle-upon-Tyne, for examples of the mischief done. In most of these places, the injury has been so great that a remedy has been called for. This remedy consists in burning the gas in such a way, that the products of combustion shall be carried off as soon as they are generated.

As regards the quantity of sulphuric acid which is produced in this manner from bisulphuret of carbon, we may say that there is some discrepancy of opinion. Mr. Lewis Thompson states that coal gas rarely contains less than the one-thousandth of its bulk of bisulphuret of carbon; and if so, 100 cubic feet of the gas can rarely produce less than 29·8 grains of anhydrous sulphuric acid. In another place he states, that he has never obtained less than 40 grains of such acid from 100 cubic feet of gas. On the other hand, Dr. Letheby asserts that he rarely obtains more than 20 grains of the acid. But let the quantity be what it may, it is evident that mischief must arise from its presence, and that the attention of chemists and gas manufacturers ought to be especially directed to the subject. The quantity of this impurity is small when the gas has been generated at a low heat; but it is large when the temperature of the retort has approached a full red, or when the charges have been kept in beyond five hours. If, therefore, no means can be adopted for the removal of the impurity after it has once been formed, it is manifest that care should be taken not to produce it.

Tarry matter is held in suspension in coal gas by means of ammonia; consequently, if we pass the gas through a small bottle or tube containing fragments of flint, moistened with dilute sulphuric acid, we shall absorb the ammonia, and arrest the tar. When coal gas, containing much tar in suspension, escapes through the fissures in the street-pipes, it impregnates the soil of the neighbourhood, and gives it a most offensive odour.

Atmospheric air is sometimes present in coal gas when the exhauster has been doing its work too energetically, or when there have been leakages in the vessels or pipes between the retorts and the exhauster. This is recognised by the blueness or thinness of the flame, and by its low illuminating power.

The Analysis of Coal Gas is rather a complicated undertaking; though a general idea may be formed of its composition by the following process:—Collect a quantity of gas in a graduated tube over quicksilver; introduce a solution of caustic potash, and agitate it with the gas for some minutes; then allow the tube to stand for a short time, and observe how much carbonic acid has been absorbed. After this has been done, pass up a concentrated solution of pyrogallic acid in potash, or, better still, a small quantity of the powdery crystals of pyrogallic acid itself; shake the tube again, and having allowed it to stand for a few minutes, read off the bulk of oxygen that has disappeared; transfer the gas to another tube over water, and by means of a syringe, or other contrivance, introduce a small quantity of bromine, or its strong solution; shake the tube for a minute or so, and observe that the bromine is in sufficient quantity to give the gas an orange-red colour; after the lapse of four or five minutes, pass up a solution of potash, and shake again. In this way the excess of bromine will be absorbed; and on allowing the tube to stand for a short time, the amount of condensible hydro-carbon may be determined by the loss in bulk. Transfer the gas to another tube, and agitate it with a solution of dichloride of copper in muriatic acid (this is made at once by mixing equal parts of black oxide of copper and recently precipitated copper, with hydrochloric acid). After a few minutes, the solution is to be withdrawn, and the gas washed with potash; the loss in bulk indicates the quantity of carbonic oxide present. Lastly, a portion of the residual gas is to be transferred to an eudiometer, and mixed with about twice its bulk of oxygen; and the mixture is to be fired by the aid of an electric spark. After standing for a few minutes, the loss in bulk is to be observed; a solution of caustic potash is then to be passed up into the gas, and the absorption of carbonic acid noted. This indicates the amount of light carburetted hydrogen present; and then by subtracting twice this volume from the total amount of diminution caused by the detonation, we obtain a number, two-thirds of which represent the hydrogen of the gas. Lastly, the residual gas, from which the portion for the oxygen experiment was taken, is to be mixed with about four times its bulk of pure chlorine, and exposed for some hours to daylight, or for a moment or two to sunlight, and then washed with potash—the residue is nitrogen. In this way we may obtain an estimate of the proportions of the chief constituents of coal gas. These, however, vary to the following extent:—

---

* Gas tar is largely employed by calico printers and dyers, in producing mauve, Magenta, and other colours.—*Editor.*

Light carburetted hydrogen,	from 35	to 52	per cent.
Hydrogen	,, 25	,, 52	,,
Carbonic oxide . . .	,, 7	,, 9	,,
Carbonic acid . . .	,, 0	,, 4	,,
Oxygen	,, 0	,, 2	,,
Nitrogen	,, 0	,, 8	,,
Condensible hydro-carbons.	,, 3	,, 20	,,

The approximative or commercial value of coal gas is determined in several ways: thus—

1st. *By means of the Photometer.*—This we have already alluded to; and it is only necessary to say here, that the methods employed are four-fold—namely, Count Rumford's plan, with shadows; Ritchie's, with his instrument that has two reflecting surfaces and a screen in a dark chamber; Wheatstone's, which consists of a mechanical contrivance, whereby a silver bead is made to revolve in such a manner as to produce a geometrical figure with two outlines; and, lastly, the plan usually employed, which is that of Bunsen's, with a waxed screen and a graduated rod—a description of which has already been given. Some doubt exists as to the kind of illuminating standard which ought to be adopted. Originally the standard was a mould candle of six to the pound; but there are so many objections to its use that it has long been discontinued. Dr. Frankland employs a composite candle; Dr. Fyfe prefers one of wax; and the standard which is specified in most of the Acts of Parliament relating to the subject, is a wax candle of six to the pound, burning at the rate of 120 grains per hour. In general, however, it is found, that there are more irregularities with the combustion of wax than with sperm; and, consequently, the latter is now almost always employed. Sometimes the comparison is made with one candle; Dr. Letheby uses two, and Mr. Evans employs three. A jet of gas composed of hydrogen and olefiant gases, mixed in the proportion of nine of the former to one of the latter, has been proposed as a standard of constant value; but the use of it is very inconvenient: and, lastly, Mr. Lewis Thompson has suggested the employment of paraffine.

Finally, it ought to be stated, that whenever the quality of gas is estimated by any of these methods, it ought to be consumed from the burner or jet which is best fitted for its combustion. If this is not attended to, a discrepancy to a large extent may arise between two different experimenters. As a rule, common gas requires a larger aperture for combustion than cannel; and high glasses, or chimneys, are apt to lower the illuminating power of the former, and to raise that of the latter. Different experimenters have exhibited different fancies with regard to this part of the subject: for example, Mr. Wright prefers a single jet, one-eighth of an inch in diameter, for his investigations; Dr. Fyfe makes use of a Winfield or Aberdeen burner; and in London, the burner fixed by Act of Parliament is an Argand of sixteen holes, with a seven-inch chimney, consuming five cubic feet per hour. There is no doubt, however, that in many cases a fish-tail or bat's-wing will afford the best light for testing purposes. We append the following table, to show how much the character of the burner affects the quality of the results obtained:—

Burner.	Consumption per hour in cubic feet.	Illuminating power.	Illuminating power per foot.
Jet five inches high . .	1·00 . .	1·00 . .	1·00
Small fish-tail	1·98 . .	2·89 . .	1·45
Large ditto	2 60 . .	4 00 . .	1·53
Small bat's-wing . . .	3·00 . .	4·40 . .	1·46
Large ditto	4·60 . .	8·40 . .	1·87
Argand of forty holes .	4·50 . .	7·84 . .	1·74

These results were obtained by Dr. Fyfe with cannel gas; and they show that the large bat's-wing produces a flame that, for equal consumption, is nearly twice as powerful as that with the single jet.

Again, the quantity of gas consumed per hour in the same burner will affect the results; thus—

Burner.	Consumption per hour in cubic feet.	Power of gas per foot.
Argand, with seventy-two holes . .	7·0 . .	5·57
,, ,, ,, ,, . .	5·0 . .	6·60
,, ,, ,, ,, . .	3·3 . .	3·40

From which it is manifest, that in ascertaining the illuminating power of gas, great judgment is necessary, both in the selection of the burner and in the rate of consumption, in order to obtain fair and proper results.

2nd. *The Chlorine test* is very much appreciated by Dr. Fyfe. It was originally proposed by Dr. Henry, and in his hands it afforded very accurate results. The objection to the test is its inconvenience; for chlorine takes a long time to prepare, and we are never certain of its being pure. Besides which, it is an unpleasant gas to inhale; and, escaping into the laboratory, it produces the most serious injury to the brass and iron-work of chemical apparatus. The mode of conducting the experiment is this:—A quantity of gas is to be let up into a graduated tube over water; the tube is then to be covered so as to exclude light, and chlorine is to be passed up into it. After standing for ten or fifteen minutes in the dark, the excess of chlorine is to be absorbed by potash, and the amount of absorption read off. The larger the quantity absorbed, the better the gas. This will range from three to twenty per cent. The matters absorbed by the chlorine are the condensible hydro-carbons, which are the illuminating principles of the gas.

3rd. *The Bromine Test.*—Many years ago, M. Balard showed that bromine had the power of absorbing olefiant gas, and that in this respect, as in most others, it was like chlorine. Lately, Mr. Lewis Thompson has taken advantage of this property, and has made it the means of discovering the quality of coal gas. The reactions of bromine on gas are exactly the same as those of chlorine; but it has an advantage over the latter, in the circumstance that it is much more manageable, that it is more likely to be pure, and that the admission of light does not affect the results. In manipulating with this liquid we fill a graduated vessel, called a Cooper's tube, with gas, and then pour into the shorter leg of the instrument a small quantity of a saturated solution of bromine in water, taking care to use enough to give the gas an orange-red colour. After the mixture has been shaken, the tube is allowed to stand for about ten minutes, and then the excess of bromine is to be absorbed by means of potash; after which, the amount of absorption is noted. As in the last case, this will range from three to twenty per cent., according to the quality of the gas.

4th. *The Sulphuric Acid Test.*—Professor Faraday long since observed, that when concentrated sulphuric acid was brought into contact with the condensible hydrocarbons, it speedily absorbed them. Relying upon this fact, Professor Bunsen has recommended that fuming or anhydrous acid should be employed for the purpose of ascertaining how much of these agents is present in coal gas. Messrs. Leigh and Frankland have spoken well of the results obtained in this manner; but however successful the process may be in their hands, it is open to many fallacies, and cannot, therefore, be recommended to the unskilful operator. The mode of experimenting is this:—The gas is to be collected in a graduated tube over mercury; and then a piece of coke or pumice-stone, fastened to a platinum wire and moistened, or rather saturated, with the acid, is to be passed up into the gas; after remaining in contact with it for ten minutes or a quarter of an hour, the coke is to be withdrawn; and, as a small quantity of sulphurous acid will have been formed by the action of the coke on the mercury, the gas is to be washed with a little potash, and then the amount of absorption noted. Sulphuric acid does not, however, attack all the hydro-carbons; for it is found that chlorine or bromine will effect a further condensation after the action of the acid. This, with other circumstances, renders the process objectionable.

5th. *The Explosion Test.*—Dr. Henry noticed that there was a direct relation between the value of a gas for illuminating purposes, and the quantity of oxygen required to burn it, or of carbonic acid produced thereby. In fact, as the illuminating power of any gas is dependent on the quantity of carbon contained in a given bulk of it, it follows that the products of its combustion must furnish a sure indication of its value. This will be manifest from the following table:—

One volume of	Oxygen required to burn.	Carbonic acid produced.
Marsh gas (CH^2)	2 volumes .	1 volume.
Olefiant gas (C^4H^4) . . .	3 „ . .	2 „
Super-olefiant gas (C^6H^6) .	4·5 „ . .	3 „
Faraday's gas (C^8H^8) . .	6 „ . .	4 „
Bicarburetted hyd. (C^6H^3) .	7·5 „ . .	6 „

So that if we mix a known quantity of any gas with about three times its bulk of oxygen, and explode them in an eudiometer by means of electricity, or make them combine by the aid of spongy platinum, as Dr. Henry suggested, the amount of oxygen consumed, and of carbonic acid produced, will serve as indications of the quality of the gas. Dr. Henry found that the best description of coal gas requires two-and-a-quarter times its bulk of oxygen for combustion, and gives one-and-a-quarter of carbonic acid; while the worst gas of his time took only eight-tenths of its bulk of oxygen, and gave but three-tenths of carbonic acid. The amount of carbonic acid produced is to be determined in the usual way by means of a solution of caustic potass.

6th. *The Specific Gravity Test.*—This is founded on the fact that the rich hydro-carbons are much heavier than the poor ones; for example, if a given bulk of marsh gas, or light carburetted hydrogen, weighs 10 grains, the same bulk of olefiant gas will weigh 17½ grains; and, in the case of the other hydro-carbons, the increase in weight is still greater. A knowledge of this fact will enable us to ascertain the value of any description of gas. We take a glass globe, or flask, fitted air-tight to a stopcock, and exhaust it with great care, by means of an air-pump; then let in pure and dry hydrogen, and again exhaust. Do this a third or even a fourth time, so as to get the flask as empty of air as possible; then weigh in a delicate balance, and note the amount: pure and dry atmospheric air is now to be admitted, and the flask is to be weighed again. In this manner we ascertain how much of pure dry air, at a temperature of 60° Fah. and a pressure of 30 inches of the barometer, it contains. When we wish to take the specific gravity of any gas, the globe is to be exhausted as before, then filled with the gas, and weighed; corrections are to be made for any abnormal difference of temperature or pressure; and then we say, as the weight of the vesselful of air is to 1, so is the weight of the gas to its specific gravity. In practice it will be found convenient to have a globe with two stopcocks, one opposite the other; so that after the first exhaustion and weighing, the globe can be easily filled with gas without the aid of an air-pump, by simply allowing the gas to pass through it for about a quarter of an hour. Mr. Wright has constructed an apparatus which still further simplifies this calculation. It consists of an oiled silk balloon that holds 1,000 cubic inches of gas; and, as coal gas is lighter than air, he determines its specific gravity by ascertaining the number of grains which the balloon will carry up. A book that accompanies the apparatus contains instructions for the management of the experiment. The specific gravity of coal gas ranges between 390 and 750. The former is about the weight of the worst gas from Garefield coals, and the latter of the best from Boghead cannel; a good average of specific gravity is 450. In conducting experiments of this kind, it must be ascertained that the gas does not contain carbonic acid, carbonic oxide, or atmospheric air; for if it does, the specific gravity of the gas is sure to be high, notwithstanding that the illuminating power may be very low.

Before we leave this part of the subject, it may be remarked, that if the specific gravity of a gas be taken before its condensation by bromine, and then again afterwards, the difference in weight will afford a means of ascertaining the specific gravity of the condensed portion; and if this be multiplied by the amount of condensation, we obtain a number that represents very nearly the illuminating power of the gas in sperm candles, as it is usually expressed. For example: a gas of specific gravity 447, has a condensation of 5 per cent., and the residual gas has a specific gravity of 328. Now since 100 cubic inches of the former weigh 13·63 grains, and 95 cubic inches of the latter 9·5 grains, the 5 cubic inches of the condensed portion must have weighed 4·13 grains, and it must have had a specific gravity of 2·7. This, multiplied by 5, the amount of condensation, gives 13·5 as the illuminating power of gas. Experiment showed it to be 14.

7th.—*The Durability Test.*—Dr. Fyfe, who is an authority in matters of this description, is accustomed to estimate the value of a gas, not only by noting its amount of condensation with chlorine, but also by observing the time that it takes to burn a given bulk of it from a jet of a given size, with a flame of a given height. The jet which he employs has an aperture of the $\frac{1}{33}$rd of an inch in diameter, and the flame is four inches in height. The first of these tests he calls the *quality* test, and the latter the *durability*. "I consider," he says, "both of these circumstances absolutely necessary; for, though some have insisted only on the one, and some on the other, yet, unless both be taken into account, we do not arrive at the true *value* of the gases, and, consequently, cannot compare one with another for the purpose of illumination." He thinks it possible that two gases may afford, by combustion, the same amount of light for the same height of flame, but that one may burn away half as fast again as the other; and, consequently, if no regard is paid to this circumstance, there will be a false estimate of their relative values. His mode of amalgamating these two powers is to multiply the per-centage of the amount of condensation by the time required to burn a cubic foot; and in this way he obtains a result that may be said to represent the true value of the gas. Suppose that one gas, which he takes as a standard, has a condensation of 4·33, and a durability of 50·5 minutes—these multiplied together make 218·7, which may be called the value of the gas. Another gas has a condensation of 7·55, and a durability of 57 minutes; these multiplied together give a value of 430·3. Now if we call the standard number of the former 1, that of the second will be 1·95; and thus we obtain their relative values. The following table is constructed on this principle:—

Gas from	Condensation by chlorine.	Durability of a cubic foot.	Relative value.
English caking coal (Newcastle)	4·33	50′ 30″	1·00
Peareth and Pelton	6·50	50′ 40″	1·50
Yorkshire Parrot	7·66	52′ 30″	1·85
English cannel (Wigan)	7·55	57′ 0″	1·93
Ramsay Parrot	12·00	62′ 0″	3·40
Mid-lothian	13·00	60′ 0″	3·56
Lesmahago	17·10	65′ 0″	5·07
Scottish Parrot	15·00	80′ 0″	5·46
Wemyss	19·50	75′ 0″	6·69
Kirkness	20·70	80′ 0″	7·75
Boghead	22·40	81′ 3″	8·32

It will be noticed, that when the value of a gas is tested in this manner, it indicates a higher quality than we can obtain by means of the photometer; but this Dr. Fyfe regards not as an error in his process, but rather as an evidence that we do not take the best means to burn the gas to the best advantage; and consequently that the illuminating power is, in the case of the richer cannels, a little below its true value.

As a corollary to the preceding, we append a table, which shows the quantity of gas furnished by different varieties of coal, together with the specific gravity of the gas, its illuminating power in sperm candles of 120 grains each, its per-centage of condensation by bromine, and its actual value in sperm candles. This table has been compiled from the results obtained by Mr. Evans, Mr. Thompson, Dr. Letheby, and others.

Coals.	Cubic feet of gas per ton.	Illuminating power.	Specific gravity.	Condens. by Brom.	Value in grains of Sperm
Boghead cannel	15,000	37·75	752	30·0	113,250
Lesmahago, No. 1	13,500	27·10	642	16·0	73,170
Wemyss	14,300	24·50	580	14·0	70,070

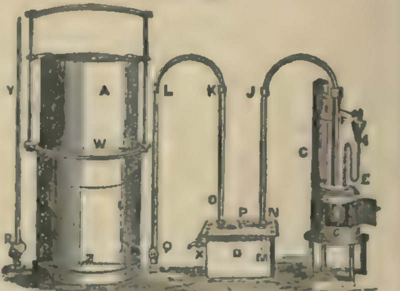
Gosforth	10,000	12·00	402	4·0	24,000

Oil Gas.—Originally this was the gas most generally in use for illuminating purposes; but the cost of its manufacture was found to be too great for its continued employment.

As far back as the year 1805, Dr. Henry published an account of some experiments which he made on a gas obtained from sperm oil, and he showed that in illuminating power it was the only one which could compete with olefiant gas. Soon after that, Messrs. J. and P. Taylor contrived an apparatus for procuring it on a large scale. Their apparatus consisted of a furnace in which was placed a twisted iron tube, containing fragments of coke. The object of this arrangement was to increase, as much as possible, the extent of the heating and decomposing surface. When the tube was red-hot, oil was suffered to run into it in a small but continuous stream. In this way the oil was decomposed and resolved into inflammable vapour, which escaped, and a fine spongy charcoal, which remained behind. The gases evolved were merely washed with water, and then collected in a gasometer. By this process it was found, that a gallon of whale-oil yielded about ninety cubic feet of gas, which had a specific gravity of 900, and was about twice as rich in illuminating principles as the best description of coal gas. Other patentees, as Mr. English, Mr. Booth, and others, followed in the same course, and endeavoured to perfect the process so as to work it on an economical scale; but notwithstanding that every means were taken to accomplish this, and that the commonest oils were used for the production of the gas, it was found that it could not compete with the cheaper gas obtained from coal: and therefore the process was abandoned.

An attempt was made to revive it by a company, which adopted the name of the Vegetable Gas Company; but the attempt has not been successful. Nevertheless, it may be said, that where coal gas is very dear, or not to be obtained at all, or where, for sanitary or other purposes, an unusually pure gas is required, then the process of making oil-gas may be practised with advantage. To meet such cases, a small apparatus has been contrived by Mr. Skelton; and a somewhat similar one is sold by Messrs. Burgess and Key, of Little Britain. The latter consists of a small cylinder B (Fig. 125), fitted into a furnace C, so that it may be made red-hot. A reservoir I, containing oil, or refuse fat, is suspended near the chimney of the furnace G, and when the fat is perfectly liquid it is allowed to drip from a small tap into a syphon pipe E, whence it runs into the red-hot cylinder, and is decomposed. The evolved gases escape by the tube F, and are conveyed by J into a purifier D, which contains water; the delivery tube M dips an inch or so under water, in order that the gas may be washed and cooled. The tube K L transmits the gas from the purifier into the gasometer A. The gas which is produced in this manner is of high illuminating power; and it appears, from the statements made by the venders of the apparatus, that a pound of kitchen-stuff yields from ten to eleven cubic feet of gas. Now a pound of this material weighs 7,000 grains; and as the gas produced weighs only about 5,000 grains, there is manifestly a loss of nearly one-third. This occurs in the form of charcoal, which remains in the retort; and hence the necessity for a frequent cleaning out of this part of the apparatus. Dr. Fyfe states that the loss in his experiments was much greater—that it amounted to nearly one-half of the fat used; and the same remark is also made by Mr. Wright, who has reported upon the comparative economy of the vegetable-gas scheme. The latter gentleman states, that for a gallon of 9 lbs., the waste amounts to 2 lbs. 10 oz.

Fig. 125.



The gas which is produced from oil is of high specific gravity, and ranges between 700 and 900. It contains from 30 to 40 per cent. of rich hydro-carbons, which may be condensed by chlorine and bromine: of these about 20 per cent. are absorbed by anhydrous sulphuric acid: 100 volumes of the gas require about 260 volumes of oxygen for their consumption, and they yield 158 volumes of carbonic acid. The durability of the gas, with Dr. Fyfe's four-inch flame from a jet the $\frac{1}{33}$rd of an inch in diameter, is 68′ 20″; consequently, its value is ten times as great as that of his standard of gas from ordinary Newcastle coal. As might be expected, the illuminating power of this gas is very high: indeed, Mr. Wright has stated that it is about four times as great as that of common gas. He reports that, with a consumption of one foot and a quarter per hour, it gives the light of twelve sperm candles, each burning at the rate of 120 grains per hour. Our own experiments, however, are not so satisfactory: they are recorded in the following table:—

Burner used.	Consumption per hour.	Illuminating power in sperm candles of 120 grs. per hour.
Small fish-tail	1·50	8
Leslie's Argand	2·25	11
Common Argand, 15 holes	3·50	14
Fine Argand, 70 holes	2·75	12
Winfield Argand	3·50	15

The advantages of this gas are, its freedom from smell; its not containing any sulphur compound; its not producing so much heat as ordinary gas for an equal amount of light; and its easy production in an apparatus which does not occupy much room. The chief disadvantage is its cost; for a shilling's worth of kitchen-stuff will only produce about 40 cubic feet of gas, which will not go farther than six or eight pennyworth of coal gas.

Portable Gas.—When oil-gas is compressed with a power of from fifteen to twenty atmospheres, it is forced into a very small bulk; and the vessels containing it may be moved about, and placed in any situation where a light is required. A company was formed some years ago for carrying out this object; and they condensed the gas in globes and cylinders which were subsequently placed in vases, columns, and other ornamental devices, so as to be completely hidden from view. Burners were fixed to the apparatus, and the gas was let out by means of a stopcock of a peculiar construction. In the act of compressing the gas, about one-fifth of its volume underwent condensation into an oily liquid; indeed, a thousand cubic feet of good oil-gas yielded about one gallon of it. This was made the subject of investigation by Professor Faraday. It is a thin oily fluid, lighter than water, sometimes transparent and colourless, occasionally opalescent, having a red tint by transmitted, and a green by reflected, light. Its specific gravity is ·821. This fluid Mr. Faraday found to be a mixture of various hydro-carbons of different degrees of volatility; and taking advantage of this circumstance, he was enabled to separate them. The great bulk of the liquid distilled at a temperature of from 176° to 190°; but a portion also came over at a temperature of 98°, and another portion required a heat of about 200° to volatilise it. These liquids consisted of carbon and hydrogen in various proportions. The most volatile was composed of equal parts of carbon and hydrogen (C^4H^4), and a part of the intermediate portion consisted of two of carbon to one of hydrogen (C^6H^3). The others were not sufficiently examined to determine their exact composition, although there was every reason to believe that they were composed, like the first, of equal atomic particles.

M. Couerbe has also examined the liquor which is produced by the compression of resin gas, and his results are quite as interesting as those of Professor Faraday. He finds that the liquid contains six different fluid hydro-carbons; five of which consist of four atoms of hydrogen and a proportion of carbon that rises in arithmetical progression from four to eight. The sixth is a compound of twenty-eight atoms of carbon and twenty-two of hydrogen.

Resin Gas.—When it was found that oil could not be profitably used for the manufacture of gas, attention was naturally directed to other and cheaper gas-producing substances. Resin was therefore selected; but it was noticed, that when this body was decomposed in the apparatus commonly employed for the generation of oil-gas, it produced a quantity of thick bituminous matter which choked the exit-pipe. This, at first, was regarded as an insurmountable difficulty; but it was overcome by the late Professor Daniell, who contrived an arrangement whereby the gas was delivered from the bottom of the retort by means of a descending pipe. His patent was taken out for this contrivance about thirty years ago, and Messrs. Taylor and Martineau were the first to put it into operation on a large scale. The retort was set in the furnace in the usual manner, and was charged with coke in order to increase the heating-surface. Across the extreme end of the retort there was a diaphragm, which was open at the top; and beyond this was the communication with the down-going delivery-pipe. The diaphragm served to prevent any of the coke from falling into the exit-tube. The resin was dissolved, or rather liquefied, by the aid of heat, in a small quantity of oil of turpentine, or of the volatile oil produced by the decomposition of the resin in a former process. The proportions were about twenty pounds of resin to a gallon of oil. This mixture was kept hot and fluid, in a reservoir placed over the fire above the retort; and when the contents of the latter were red-hot, they were allowed to run through a syphon tube, and to drop upon the incandescent coke at the nearest end of the retort. The vapours which were thus produced passed along the whole length of the retort, and were completely decomposed before they escaped over the diaphragm into the descending pipe. A part of these vapours was liquefied by the cold of the condenser, and such appeared as a limpid volatile oil; the other portion passed on as gas; and, after having been purified by washing with lime-water, was collected in the gasometer. This process of Daniell's was considered to be very complete, though it has been modified in certain particulars by subsequent patentees: thus, Mr. Richardson has proposed that the resin should be mixed with sawdust and some alkali, as lime, potash, or soda; and that it should be put into the retort in thin sheet-iron vessels of a cylindrical form. In these the first distillation takes place, and the volatile products are conveyed into other vessels, or retorts, charged with coke, lime, or broken bricks, kept at a red heat. By these means it is thought that more gas, and less volatile oil, are obtained. Mr. Webster generates the gas in another way. He passes the vapour of coal-naphtha over a bed of heated coke, and thence over a quantity of melted resin. The volatile matters so obtained, traverse another vessel filled with incandescent coke, and there they undergo decomposition.

A pound of resin will yield about ten cubic feet of gas; or, more correctly speaking, a hundredweight of resin will furnish from 1,000 to 1,200 cubic feet of gas, and about three gallons of oil. The gas has a specific gravity of from 660 to 850; and its illuminating power is but a little inferior to that of oil-gas. When it is imperfectly made, it does not contain more than eight or ten per cent. of condensible hydro-carbons; and it was found by Dr. Fyfe to have a durability of fifty-three minutes and twenty seconds: its value, therefore, is about the same as that of gas from Wigan cannel. As in the case of oil-gas, this illuminating agent does not contain a particle of any sulphur impurity.

Although the production of gas from resin is not practised in this country, in consequence of the more economical source of coals, yet in many parts of America, where resin and crude turpentine are cheap and abundant, the process is still worked with advantage.

Hydro-carbon Gas.—This name is given to the mixed gases which are generated from water, together with substances that are rich in hydro-carbons, as tar, resin, fats, oils, and the better kinds of cannel coal.

Although this description of gas has but recently been made on the large scale, yet the principles of its manufacture were known and appreciated many years ago. In the year 1830, Mr. Donovan took out a patent for the generation of gas from steam, by passing it over red-hot coke or charcoal, and subsequently naphthalising it at the burner, by means of turpentine or coal-tar. Since that time many improvements have been made in the process: and we may refer to the names of Manby, Val-Marino

Radley, Lowe, White, Croll, Webster, Barlow, and Gore, in proof of the number of persons who have taken out patents in this country for the generation and naphthalisation of water-gas. In every case the water, or rather the steam, is decomposed by passing it over red-hot coke or charcoal; and it is subsequently naphthalised by passing it over rich hydro-carbons.

The details of the process vary with the nature of the materials used. When fat and resin are employed, the process, as described by Mr. White in his patent, is as follows:—Two retorts, about seven feet long and nine inches in diameter, are set vertically in a furnace so that they may be heated to full redness, or even to an incipient white heat. A flue passes through the centre of each of the retorts, in order that the contents may be thoroughly heated. They are packed full of coke, charcoal, or anthracite, and a few scraps of iron. When the retorts are red-hot, water is allowed to flow through a syphon upon the top of the ignited mass. The steam which is thus generated, passes over the red-hot coke, and is decomposed into hydrogen and carbonic oxide, which is incidentally attended with more or less of carbonic acid. The gases and vapours thus produced, escape from the bottom of the retorts into two others placed horizontally in the same furnace. These are about six feet long, and are divided into two or more compartments by longitudinal divisions which reach nearly to the end. The compartments are filled with coke, chains, or coils of iron wire, so as to increase the surface; and into the first of these, tar, fat, or resin is allowed to flow, so as to undergo decomposition. The evolved gases are rapidly carried off and mixed with the gaseous products of the first retort; and after they have passed through a condenser and a lime purifier, they go on to the gasometer. In working the process, the supply of the materials should be so managed, that the gaseous mixture should consist of about four parts of water to six of the material. When resin is used, the proportions of the various materials are, one hundredweight of resin, seven-and-a-quarter gallons of resin-oil, fifteen pints of water, a sixth of a bushel of charcoal, and a few ounces of scrap iron. These produce from 1,500 to 1,600 cubic feet of gas, and about three gallons of oil. Dr. Frankland has entered into a very detailed examination of this process; and it appears from his report, that a hundredweight of resin, with from thirty to forty pints of water, will yield from 1,500 to 1,900 cubic feet of gas, and from two to four gallons of oil. The temperature at which the best results are obtained is that of dull redness; for if the heat be carried much above this point, the richer gases are decomposed, and changed into several gases of low illuminating powers. He found that two distinct changes were effected in the water-retorts. In one case the steam was decomposed by the red-hot charcoal, and equal volumes of hydrogen and carbonic *oxide* were indirectly produced; in the other, it was converted into two volumes of hydrogen, one of carbonic *acid* being also evolved. These mixed gases, together with some undecomposed steam, pass into the resin retort, where they mix with the vapours of the decomposing resin, and pass twice along the length of the red-hot retort. Here the steam is again subjected to decomposition by the agency of the fuliginous matter evolved from the resin. This change is a very important one, for it prevents the accumulation of carbon in the exit-pipe of the retort. If the gas be examined at this stage of its manufacture, it will be found to contain a very large proportion of carbonic acid; and one of the greatest difficulties in the subsequent management of it, is the removal of this impurity. Ordinary wet lime will only remove a portion; and hence Dr. Frankland has recommended the use of caustic soda, which may be produced by the admixture of carbonate of soda with cream of lime.

The gas which is thus produced has a specific gravity of from 600 to 660. It contains from seven to eight per cent. of condensible hydro-carbons; and its illuminating power is about the same as that of ordinary cannel gas. Its composition is as follows:—

	Ordinary gas.	Pure gas.
Condensible hydro-carbons	7 41	8 13
Light carburetted hydrogen	26·50	29·71
Hydrogen	40·27	43·38
Carbonic oxide	18·55	18·78
Carbonic acid	7·27	0·00
	100·00	100·00

According to Dr. Frankland's report, hydro-carbon gas, from steam and resin, may be manufactured at from 9½*d.* to 1*s.* 1½*d.* per 1,000 cubic feet. This is irrespective of the cost of the apparatus, or of the charge for wear and tear.

When the gas is made from rich cannel coal, the arrangement of the apparatus is a little different from the preceding. In such cases the patentee adopts the following plan:—

Both retorts are placed horizontally, and they are divided into two compartments by means of a longitudinal septum that reaches nearly to the end of each. These, called the water-retorts, are charged with coke; and after being raised to a high temperature, water is allowed to fall gently through a syphon-pipe upon the red-hot coke at the outer end of the upper compartment. The steam which is thus generated passes through the ignited contents of the upper compartment, and thence descending behind the septum, it comes forward through the lower. By these means it is exposed to a large surface of red-hot charcoal, and is in great part decomposed, and hydrogen, carbonic oxide, and a little carbonic acid are produced, all of which enter the lower compartment of another retort, which is charged with cannel coal. Here they mix with the various hydro-carbons that are evolved from the coal; and after traversing the retort from one end to the other and back again, they pass into the condenser and wet-lime purifier, and thence into the gasometer. Dr. Frankland states, that by this mode of working, all the carbonic acid which is generated in the water-retort is decomposed by the fuliginous matter of the coal, and converted into twice its bulk of carbonic oxide. It is thought, also, that the water-gases exert a conservative influence on the rich hydro-carbons which are evolved from the coal; and that by sweeping them away as fast as they are produced, and so protecting them from the destructive agency of heat, a much larger quantity of illuminating matter is obtained.

Dr. Frankland has examined the value of this process, as applied to different varieties of cannel coal. He worked with one hundredweight of each of the following coals, and he obtained the following amounts of mixed hydro-carbon gases. The coals were placed in each of the compartments of the second retort, and they were distilled at a low red-heat. The water-gas was obtained in the usual manner:—

Name of coal.	Yield per ton.	Illuminating power of the gas in sperm candles.
Wigan (Ince Hall)	16,120	20·0
Ditto (Balcarres)	15,500	19·1
Newcastle cannel	15,020	18·8
Methyl	26,400	21·0
Lesmahago	29,180	28·7
Boghead	51,720	17·9

The illuminating power was tested in the usual way with a No. 4 fish-tail burner, consuming five cubic feet per hour, at a pressure of half an inch of water; and the candle was a sperm candle, calculated to the amount of 120 grains per hour. According to Dr. Fyfe's mode of estimating the value of the gas, an average sample has a durability of 43 minutes and 20 seconds, and its amount of condensation by chlorine was 11·44 per cent.; so that its quality was about 2¼ that of ordinary gas from Newcastle coal.

Mr. Clegg speaks highly of the value of this process. He says that a ton of Wigan coal yields, under ordinary circumstances, about 10,000 cubic feet of twenty-candle gas; while with the hydro-carbon process it furnishes 16,000 cubic feet of gas of the same quality, and 26,000 cubic feet of twelve-candle gas. A ton of Lesmahago cannel produces, in the usual way, 10,500 cubic feet of forty-candle gas; but with the hydro-carbon process it will yield 36,000 cubic feet of twenty-candle gas, or 58,000 cubic feet of twelve-candle power; and a ton of Boghead, which generally furnishes about 13,500 cubic feet of forty-candle gas, will by this process give as much as 52,000 cubic feet of twenty-candle gas, or 75,000 of twelve-candle. From which it is manifest that, although there is a comparative reduction of the illuminating power in consequence of the diluting power of the water-gas, yet, on the whole, there is a considerable increase in the amount of illuminating material. This increase varies from 50 to 100 per cent.; and it is, no doubt, due to the property which water-gas has of suspending the volatile hydro-carbons which are generally condensed in the tar.

Mr. Clegg states, that the cost of working the process is not very considerable, for gas of twenty-candle power may be obtained from Wigan coal at the rate of 1*s.* 3½*d.* per 1,000; from Lesmahago at 11¾*d.*; and from Boghead at 11*d.*: besides which, the gas is remarkably free from every kind of sulphur compound. The conclusions at which Dr. Frankland has arrived, after having made a very careful examination of Mr. White's process, are the following:—

1st. That it greatly increases the produce of gas from a given weight of coal, the increase being from 46 to 290 per cent., according to the nature of the material operated upon.

2nd. That it greatly increases the total amount of illuminating power, the increase being from 12 to 108 per cent.

3rd. That it diminishes the quantity of tar formed, by converting it into gases of high illuminating power.

4th. That it affords a means of reducing the illuminating power of gases which could not be profitably burnt alone: and,

5th. It may be easily applied to any of the apparatus or modes of working now in use.

In opposition to these conclusions must be placed the results obtained by Messrs. Brande and Cooper, who found that little or no advantage was gained by the process; and Dr. Fyfe, who is much opposed to the whole scheme, states that, when all things are considered, it is a process which ought at once to be abandoned. Mr. Barlow has, however, recently examined the merits of the process; and he believes that, with some few alterations in the way of working, it may be profitably carried out. His suggestion is to collect the water-gas in separate gasometers, and to convey it from them, instead of from the retorts, into the compartments where the coal is distilling.

Water-gas alone.—Several patents have been taken out, at various times, for the production of gas from water, and for the employment of such gas either alone, as when it is wanted for heating purposes, or in combination with the vapour of naphtha. Donovan's patent, of 1830, we have already alluded to. M. Floret has contrived an arrangement for decomposing steam, by means of coke heated to a high temperature in an atmosphere of oxygen. Mr. Paine, of America, says he decomposes water by the aid of electro-magnets; Mr. Adams, of Boston, effects it by the force of a galvanic battery; and Mr. Shepard assists the action by using a salt of ammonia, or a vegetable acid, as the oxalic. In Mr. Gillard's process, steam is decomposed by passing it over incandescent charcoal, in such a manner as to form hydrogen and carbonic acid; the latter being absorbed in the usual way by means of caustic lime. All these patents, however, are but so many examples of fruitless speculation; and they may be pointed at as illustrations of so-called unsound chemical knowledge, combined with the worst kind of practical experience.

As the hydrogen and carbonic oxide produced by either of these processes does not possess the smallest amount of illuminating power, it must be brought up to the required standard, either by passing it through a volatile hydro-carbon, or by burning it in such a way as to make a solid incombustible body white-hot. Mr. Gillard adopts the latter contrivance; and his plan is to consume the gas from an Argand burner, over which there is suspended a rosette of platinum wire. The wire becomes intensely heated; and, when the gas is burning at the rate of six-and-a-half cubic feet an hour, the light emitted is about equal to five composite candles, or to that of a fish-tail consuming three feet of ordinary gas per hour.

Wood Gas.—When wood is subjected to distillation in closed iron vessels, it evolves a large quantity of inflammable vapour, some of which condenses into a liquid form, while the rest passes off as combustible gas. The liquid consists of water, pyroligneous acid, naphtha, and a complex heavy tar; and the gas is composed of hydrogen, carbonic oxide, carbonic acid, light carburetted hydrogen, and a variable proportion of olefiant gas. When these are consumed in the ordinary way, they do not produce much light; but if they are passed through a volatile hydro-carbon, they may be brought up to any degree of illuminating power. It is possible, also, that by certain modifications of the process whereby they are obtained, a sufficient amount of rich hydro-carbons may be generated, to do away with the necessity for subsequent naphthalisation. Mr. Hills proposed to mix the gases which are obtained during the manufacture of crude pyroligneous, with those which result from the destructive distillation of coal-tar; and Mr. Lowe has taken out a patent for the use of tar, oil, resin, or cannel coal, as a means of giving illuminating power to the gases evolved from sawdust, spent bark, or peat. Other patentees have suggested that the sawdust and tar should be mixed together before they are distilled; but it does not appear that any of these schemes have been successful in practice, or have been able to compete with the more economical mode of obtaining gas from coal. On the continent, however, where wood is very abundant, and coal scarce, it is frequently more profitable to make gas from the former than from the latter. At Bâle, for example, and some other towns of Switzerland, Norway, and Sweden, the process of distilling gas from wood is practised on a very large scale. We are told that the old city of Heilbronn has recently been lighted up with wood-gas; the manufacture of which is under the management of M. Schäufelen, who produces a gas of very good illuminating power. It is said that a fish-tail burner, consuming four-and-a-half cubic feet per hour, gives the light of thirteen wax candles; and that one of five cubic feet an hour, produces the light of sixteen candles; while an Argand burner, on Dumas' construction, consuming the same amount of gas, evolves the light of twenty candles. If this be so, it is evident that wood-gas can be obtained of a quality superior to that of ordinary coal gas.

Peat Gas.—This is nearly of the same composition as the gas evolved from wood; and the collateral products are nearly of the same description and value. Many chemists have, at different times, devoted their attention to this subject; but it is only very recently that precise information has been obtained concerning it. Sir Robert Kane in Ireland, and Dr. Letheby in England, have each reported on the quality of the products generated during the destructive distillation of peat; and from their statements it appears, that 100 parts of peat will furnish from 10 to 40 of charcoal, from 2 to 5 of tar, from 11 to 38 of aqueous matters, and from 25 to 58 of gas. The charcoal is very valuable as a decoloriser and disinfectant; the tar is rich in paraffine and creosote; the watery fluids contain ammonia, acetic acid, and wood-naphtha; and the gases consist of hydrogen, carbonic oxide, carbonic acid, and various hydro-carbons. One thousand parts of peat will yield, on an average, 2·7 of ammonia (equal to 10·4 sulphate), 1·9 acetic acid, 1·4 wood-naphtha, 7·9 volatile oils, 5·5 fixed oils, and 1·4 paraffine. From Dr. Letheby's experiments, it appears that a ton of peat will furnish about 13,000 cubic feet of gas, the illuminating power of which is equal to seven standard candles, when the gas is burned from an Argand that consumes five cubic feet per hour; but the intensity of the light may be brought up to any degree by the usual process of naphthalisation. As peat is very abundant, its products valuable, and its gas entirely free from sulphur, it is very probable that it may be used with great advantage as a source of inflammable gas: in fact, a patent has been taken out by Mr. Hansor of London, for the manufacture of an illuminating gas from a mixture of 12 parts of peat, 12 of resin, 8 of coal-tar, and 16 of oil. This is effected by distilling the mixture from perforated iron boxes, placed in a furnace heated to a cherry-red; the condensible vapours so produced are then passed through another furnace divided by diaphragms, and raised to a bright red-heat. By this they are decomposed, and rendered permanently gaseous. The gas so obtained, after having been purified by means of lime, has a density of ·626, and its illuminating power is a little higher than that of common cannel gas, or about twice as great as that of ordinary coal gas. A fish-tail burner consuming 2·5 cubic feet per hour, gives the light of 9·2 standard sperm candles; and an Argand consuming 3·5 feet, gives the light of 15·5 candles. One of the great advantages of the gas is its perfect freedom from every kind of sulphur impurity. A company has been formed, under the name of Hansor's Olefiant Gas Company, for carrying the patent into full operation.

Gas from Wine Lees and Grape Skins.—These substances are said to produce a very good gas. One pound weight of either of the materials will furnish seven cubic feet of gas of more than ordinary quality. This fact was demonstrated in the year 1849, by M. Levenair of Bordeaux, and Dr. Berhardt of Paris, in one of their public lectures before the Faculty of Sciences. If the results be uniform, the process affords an easy means of obtaining gas, and other valuable products, from a material that has hitherto been used only as a manure; besides which, the residue of the distillation is just as valuable to the wine-grower as the lees themselves.

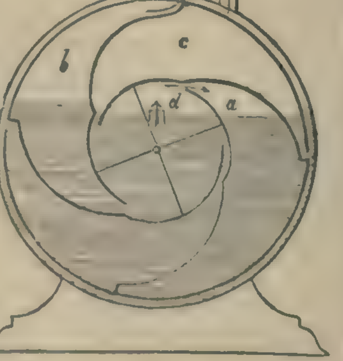
Gas from Coal Tar.—This liquid has very frequently been made the subject of experiment, in the hope that the rich hydro-carbons which it contains might be converted into permanent gases of high illuminating power; but, hitherto, all attempts at effecting this desirable result have signally failed. In the year 1820, Mr. Lowe contrived an apparatus for decomposing coal-tar, and resolving it into permanent gases. It consisted of a furnace with five retorts, three of which were placed below, and two above. These were charged in the ordinary way with coal; and when the carbonisation had gone on for three hours, the tar was allowed to flow through a syphon-pipe into the back part of the upper retorts—these being the hottest. Here the tar was converted into vapour, and it passed over the incandescent surface of the charge to the front of the retort, where it escaped through the exit-pipe to the hydraulic main. According to Mr. Lowe, he was enabled to produce, by this arrangement, a maximum quantity of gas of high illuminating power; but, although the process was worked upon a very large scale under the immediate superintendence of the patentee, it did not succeed, and it was soon abandoned. Since that time a number of patents have been taken out for a like purpose; but none have been successful. In some cases the tar has been mixed with small coals; in others with peat; in others with sawdust; and, very recently, Mr. Way has proposed the use of a porous stone, which he saturates with tar. Some have distilled the material at a low heat, others at a moderate temperature, and others at a very high one: so that every species of ingenuity has been exhausted in endeavouring to convert this rich inflammable fluid into a permanent gas.

Other organic substances have been resorted to as a source of gas. M. De Cavaillon has proposed a mixture of bones, suet, oleaginous seeds, spent bark, sawdust, molasses, and small coal. Mr. Booth has claimed the use of resinous woods and oily seeds. Mr. Witty has patented a mixture of vegetable oils, and refuse vegetable matters, such as spent hops, dry peat, or dry sawdust, which he presses into blocks, and distils in earthenware retorts; and then, again, it may be said that Mr. Lowe has obtained a patent for naphthalising gases from any source, by passing them through a vessel containing coal-naphtha—a process that was suggested many years ago by Dr. Henry, of Manchester. Lastly, Mr. Archibald has gone so far as to naphthalise atmospheric air in a somewhat similar way. He first saturates the air with moisture, and then conveys it through benzole, which is the most volatile of the coal-naphthas. He also passes the air through a mixture of one part of benzole, two of alcohol or wood-spirit, and one-and-a-half of water. By this means the air acquires inflammability, and may be burnt from an ordinary gas jet: it may even be stored in gasometers, and distributed in the same way as coal gas. If the air is not saturated with moisture, so much cold is produced by the volatilisation of the benzole as to stop the process of naphthalisation; and hence the necessity for adding water to the hydro-carbons.

ON THE APPARATUS REQUIRED FOR THE CONSUMPTION OF GAS.

The Gas-meter.—When gas was first used by the public, it was sold at an annual rent, at so much per burner; but it soon became apparent that this was not a fair mode of dealing with the article, and hence the ingenuity of the mechanic was taxed to contrive a means whereby the gas might be accurately measured. This was accomplished by Mr. Clegg, who, in the year 1815, constructed the first meter. In the following year he improved it so far as to obtain a patent for it. At first Mr. Clegg attempted to register the gas by means of two small gasometers, which rose and fell alternately, one receiving the gas while the other was delivering it. But this plan was not successful, and it was, therefore, abandoned for another which constitutes the basis of all the wet-meters that have been contrived since Mr. Clegg's time. It consisted of a drum, which revolved in a chamber half filled with water. The drum was divided into two compartments, one of which received the gas while the other delivered it. The gas entered through the hollow axis of the instrument; and as the drum revolved and submersed the compartment, the gas was forced through a lateral opening into the outer chamber, and thence to the burners. By means of valvular contrivances, two of which were closed by water and two by springs, the gas was made to flow only in one direction; but as the spring-valves were easily thrown out of order, and the water-valves were of a clumsy form, the instrument was open to very great improvement. Mr. Malam, therefore, in 1819 reconstructed the apparatus. He divided the drum into five compartments—one of which was central, and the others around it (Fig. 126). As in Mr. Clegg's instrument, the gas entered the apparatus through the axis of the drum; but in order that there should be no friction or impediment to its movement, he did away with the stuffing-box in which it worked, and brought the central tube or axis, by means of a rectangular bend, up above the level of the water in the central chamber *d*. He also put aside the clumsy water-valves and the too delicate spring-valves of Clegg's instrument, and adopted a simple contrivance whereby the delivery apertures were made to act of themselves by simply rising above the level of the water. These apertures were in the form of slits, which communicated first between the central chamber and the circumferential ones, and then between the latter and the outer case. On entering the central compartment, the gas escapes through whichever of the first set of slits

Fig. 126.



happens to be above the level of the water. In the figure it is passing from *d* into *a*. This gives a buoyancy to that chamber; and as it rises or floats, it turns the drum round from right to left, causing the gas which is in the upper and descending compartments to escape through their outer slits into the outer chamber, and thence to the burner. It will be noticed that, as the drum revolves, the entrance-slits between the middle and outer chambers are successively carried under the water, and that as soon as this happens, the exit-slits in the circumference of the drum are each in their turn brought out of it. This is shown in the figure as about to occur with compartment *c*, whose entrance-slit is just dipping under the water, while the exit-slit is rising out of it. Since the time of Mr. Malam, other improvements have been effected in the details of this meter; by means of which the revolution of the drum has been made steadier, the amount of friction lessened, and the water kept at one uniform level. Among the names of those who have devoted attention to the subject, are Crosley, Wright, Evans, Hulet, Smith, Paddon, and Ford; all of whom have, in some particular or another, improved the instrument.

Fig. 127.

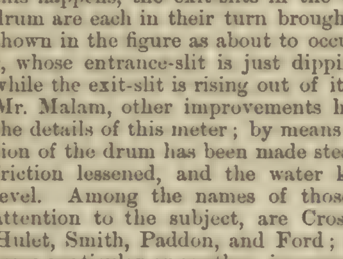


Fig. 128.

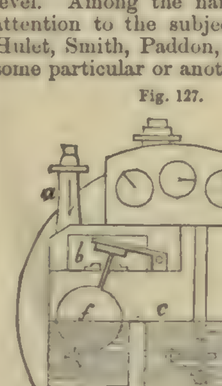


Figs. 127 and 128 represent a meter of modern construction, with most of the improvements adopted. The gas passes by the inlet-pipe *a* into the chamber *b*, whence there is a communication by means of a flat valve with the compartment *c*; from this it passes through the bent pipe, forming the axle of the drum, into the compartment *d*, and thence, in the manner already described in Malam's meter, it gets into one or other of the four compartments, and so escapes by an exit-slit into the space formed by the surrounding case: *f* is a ball which floats on the water, and keeps the flat valve open. If the water gets below its proper level, the ball falls; and by bringing down the valve, shuts off the gas. *g* is a tube for passing water into the cistern, and *i* is a waste cistern for receiving the water when it gets above the proper level and flows over: *h* is a syphon-tube for drawing off the water which has been added in excess. By a train of wheelwork, the revolutions of the drum are communicated to the hands on the dial-plate; and thus the quantity of gas consumed is registered.

There are two objections to the wet meter, which are insurmountable. These are, that the instrument registers the vapour of water as well as gas; and, secondly, that it is very liable to stop, at an unexpected moment, by the deficiency of water and the sinking of the float. When a meter is placed in a warm situation, the quantity of aqueous vapour that is registered by the instrument, and set down as gas, is very considerable; and if it should so happen that the gas, after passing the meter, has to traverse a cold locality, the aqueous vapour will be recondensed as water, and will cause a flickering of the flame, or even a total closure of the pipe.

At one time it was possible for the gas companies to derive an advantage from the overfilling of the water-cistern, whereby the capacity of each measuring chamber was somewhat diminished; and thus a revolution of the drum did not record a proper quantity of gas. It was also possible for the company to be defrauded by a deficiency in the amount of water; but now both of these objections are guarded against by the waste-tube and cistern on the one hand, and by the float-valve on the other.

It will be seen, by an examination of the meter represented in Fig. 126, that, by tilting the meter a little on one side, the gas will pass through the slits of the uppermost chamber without turning the drum at all, and frauds are sometimes committed in this manner; but the experiment is a very dangerous one, and is not likely to be practised by any but the most determined rogue.

The *dry-meter* is a more complicated apparatus, though it consists in all cases of a chamber, or set of chambers, with flexible leather sides. The action is very similar to that of a pair of easy-going bellows; and the movement is communicated to levers and rack-work, which not only register the amount of gas that passes, but, by a set of sliding-valves like those of a steam-engine, they also cut off the supply of gas from one chamber, and turn it on into another.

The first dry-meter was patented by Mr. Malam in 1820: it consisted of a set of six bellows placed in a radiating direction around a common centre, the whole being inclosed in an air-tight chamber. These bellows worked successively one after the other, and they communicated their motion to a set of wheels, which served to register the quantity of the gas delivered. This machine was, however, not perfect—it had many radical faults; and hence it did not come into general use. Next after this was the instrument constructed by the Dry-Meter Company. The measuring chamber was formed of leather, which was found to be liable to many objections; for if the meter were used constantly, the leather expanded under the influence of the gas, and so it recorded against the interest of the company; whereas, if it were not used so constantly, it underwent contraction, and then it registered against the consumer: besides which, the valve moved so suddenly from one side to the other as to produce an unsteady flame, and hence the meter was not much patronised. Sullivan's meter, which followed upon this, was open to the same objections; for it consisted of two loose leather diaphragms and a rotatory valve. In 1833, an American, by the name of Berry, patented an instrument which was invented by a person named Bojardin. The meter was a hollow chamber, which had a movable diaphragm or partition that divided it into two compartments, and, by means of sliding-valves, the gas was alternately let in or out of them. In 1836, Bojardin invented a still better machine; and he is looked upon as the originator of the present form of dry-meter. Since that time, Mr. Defries, Mr. Edge, and Mr. Croll have improved the instrument, and brought it into its present condition. Mr. Defries' meter contains three measuring chambers, which are separated from each other by a flexible partition formed of leather, and partially protected from the action of the gas by four triangular metal plates, which almost cover the diaphragm. This flexible partition is raised or depressed by the gas, so as to form a pyramid or a flat surface; and the rise and fall of the partition is communicated to the wheelwork of the apparatus; but, as in all cases where leather enters into the construction of the measuring chamber, the instrument is very liable to register incorrectly. The meter which is manufactured by Messrs. Croll and Glover is said to be free from this objection: its construction will, perhaps, be understood from the following account, taken from Mr. Croll's paper, which was read before the Society of Civil Engineers in 1845. "If we imagine a steam-engine measuring its steam by the movements of the piston, we shall have some idea of the principle of the instrument. The steam enters the cylinder over the piston, and forces it down through a certain space; the supply is then cut off, and the action is reversed. Now, suppose the piston to be of a given area, and the distance through which it moves at every stroke to be constant, it can readily be conceived how the actual quantity of steam employed could be indicated and calculated. The meter in question bears a strong resemblance to a double engine: it consists of a cylinder divided by a plate in the centre into two separate cylindrical compartments, which are closed at the opposite ends by metal discs; these discs serve the purpose of pistons, and they are kept in their places by a kind of universal joint adapted to each. The space through which the discs move, and consequently the means of measurement, is governed by metal arms and rods; which space, when once adjusted, cannot vary. To avoid the friction occasioned by a piston working in a cylinder, a band of leather is attached so as to act as a hinge. This folds with the motion of the discs, but it is not in any way concerned in measuring the gas; so that if it were to contract or expand, the registration of the proper quantity of gas would not be affected; for such a change would only decrease or increase the capacity of the hinge, leaving the disc still at liberty to move through the required space. The leather is also attached in such a manner as to avoid folds, and thus to render it more durable.

Gas-burners.—Scarcely anything connected with the subject of gas illumination has commanded more attention than the means whereby gas may be burnt to the best advantage; and although the greatest ingenuity has been displayed in the construction of many of the burners which have at different times been invented, yet none of them possesses that universal applicability for which they have in most cases been so highly vaunted. The reason of this is obvious: different kinds of gas require different forms of burners, in order to effect perfect combustion. As a rule, it may be stated, that the rich cannel gases are best consumed from burners with very fine apertures: while the poorer gases—namely, those which contain less than five or six per cent. of condensible hydrocarbons—are burnt with most advantage from larger apertures. Again, in the former case, provision should be made for a large supply of atmospheric air, as by spreading out the flame by means of an internal button, or by using tall glasses; whereas, in the latter case, the very opposite condition should be observed. It is manifest, therefore, that no single burner can be constructed so as to secure both of these requirements; and, consequently, that any burner which is well suited for one kind of gas, is altogether unfit for the other.

Another point of importance to which we may refer in speaking of this subject, is the following:—that when several jets issue from the same burner, and blend together or coalesce, the light is always improved; for it is the property of one jet to assist another by exalting its temperature; and thus a greater heat and a brighter flame are the result of the union—more light being given out than is the sum of the individual jets. It is on this account that the Argand burner, the fish-tail, the Gaumont, and the Gardner, have obtained preference over many other forms of burners.

Lastly, it may be stated, that in whatever way gas is consumed, the maximum effect, as regards its illuminating power, is always produced by burning the gas just short of its smoking-point: for if it be burnt with too much air, the particles of carbon are consumed; and we thus obtain a diminishing light, until the flame becomes of a pale-blue colour. On the other hand, if it be burnt with too small a supply of atmospheric air, the particles of carbon will not be sufficiently consumed, and they will escape as soot—thereby cooling the flame, and making it of a dingy yellow tint. Our object, therefore, should always be to burn the gas in such a manner that the particles of carbon may be first intensely heated, so as to produce a white light; and then, as they reach the exterior of the flame, they ought to be consumed entirely, so as to avoid the evolution of soot. Of the different varieties of burners now in use, the following are the most important:—

1. *The simple jet* is produced from a burner pierced with a single hole. This mode of consuming gas is not considered to be cleanly or economical; and, except for certain purposes of illumination, as where we wish to produce different kinds of devices, it is rarely employed. Occasionally it is used in the laboratory of the chemist for experiments with the blowpipe, as it is found to give a much hotter and clearer flame with this instrument than any other form of jet. The average consumption of a jet the thirty-third of an inch in diameter, with a flame four inches high, is about one cubic foot per hour. With richer gases the quantity is a little less, and with very poor gases it is somewhat more. As we have already said, Dr. Fyfe prefers a jet of this description for the purpose of estimating the illuminating power of gas; and, in a general way, it is equal to from one to one-and-a-half, or two sperm candles.

When it is necessary to produce a greatly diffused light, it may be accomplished by means of one or more rows of single jets. These may be distributed around the cornice or mouldings of a room, and the effect is remarkably pleasant and agreeable, for there is a flood of light without the least glare or shadow. The only objection to it is its great cost and its liability to evolve smoke; but if these were overcome, and our rooms constructed so as to have a row of lights around a panel in the ceiling, there is no doubt that the effect would be much more pleasing than that which results from our present mode of burning gas; besides which, the panel might be so arranged as to convey away the products of combustion, and thus the effect would also be more salutary.

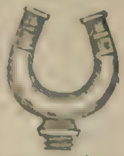
2. *The Cockspur Burner* is a burner with three or more jets radiating off from it, and burning separately. The light from such a burner is only equal to the sum of the individual jets; for as they do not coalesce, they cannot in any way assist each other. It is one of the worst forms of burner that can be employed. A burner with three jets, consuming three cubic feet per hour of ordinary London gas, gives a light of from five to six candles.

3. *The Fish-tail* or *Union Burner* is so named because of the form of its flame, and because of the manner in which it is produced by the union of two jets. It is formed by drilling two holes at an angle of about 60°. The jets are directed into each other; and as they coalesce, they spread out so as to produce a flat sheet of flame of the form of a fish-tail: by this means the intensity of the light is greatly increased. The holes are drilled large or small, according to the quality of the gas to be employed. In the case of cannel gas, the holes are small; and for common London gas they are rather large. The former are known by the name of Lancashire or Scotch fish-tails, and the latter as London jets. Each sort is numbered 1, 2, 3, or 4, according to the size of the holes; and these numbers are indicated by means of little rings turned on the body of the jet. No. 1 is the smallest. These burners consume from two to four cubic feet of gas per hour; and with cannel gas they give the light of from eight to fourteen candles, and with common gas, of from four to ten.

4. *Johnson's Burner* is a fish-tail with four converging holes; and there is an aperture through the centre of the burner for the admission of atmospheric air into the flame.

5. *Billow's* or *Gardner's Burner.*—This is a combination of two fish-tail or bat's-wing burners, arranged so as to produce one flat flame (Fig. 129). The flames impinge on each other, and thus increase the illuminating power by about thirty per cent. These burners are usually constructed of two fish-tails; and occasionally, for experimental purposes, they are attached to a hinge-joint, so that the flames may be burnt separately or together. As in the case of the ordinary fish-tails, they are numbered 1, 2, 3, and 4. No. 1 consumes about three cubic feet per hour, and No. 4 about five.

Fig. 129.



6. *The Bat's-wing Burner* is so named on account of the shape of the flame. It is one of the oldest forms of gas-burners; it is constructed with a slit instead of two holes for the exit of gas; and the flame is broader, and not so high as the fish-tail. These burners are easily managed, and on this account they are generally supplied to the public lamps. They burn from three to five cubic feet per hour; and, with a consumption of four cubic feet per hour, they give the light of about nine sperm candles of standard quality.

7. *The Gaumont Burner* is a bat's-wing burner with two or three slits, instead of one. By means of this contrivance there are two or three flames amalgamated into one; and, as is always the case under these circumstances, the total amount of light is increased. A Gaumont, which consumes three cubic feet per hour, gives the light of seven sperm candles.

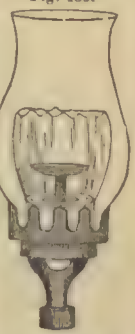
8. *The Sun Burner* is a cluster of fish-tail burners, usually nine in number, placed round a common axis, and spreading out in a horizontal direction, so as to produce the figure of a flower or of the sun. This burner is so constructed, that the products of combustion are carried out of the room by means of a ventilating funnel and tube placed immediately over it; and the air which supplies the flame is made to descend through the ventilating tube, and thus to become very hot before it reaches the burner. By this arrangement there is a great saving of gas. In most cases the sun-burner consists of seven clusters of nine fish-tails each. The burners are supplied with gas by a descending-pipe, which branches to each cluster; and, surrounding the whole, is a sheet-iron cone, with a tube attached to the top, for carrying off the products of combustion. In this tube there is placed a butterfly-valve, for the purpose of regulating the current of air, so that the draught may not be too great, and the lights may burn in a horizontal direction. Around the cone are placed three other sheet-iron cases, which not only serve for ventilation and for the supply of air to the burners, but also insulate the inner cone, and by their cooling effect, prevent the intense heat of the latter from being communicated to the woodwork of the ceiling. These cylinders are not connected with each other, or the cone, and, therefore, distinct currents of air pass between each of them; and such is the cooling effect of these currents, that, while the cone is red-hot, the two outside cases are of the same temperature as the atmosphere of the room. On the upper part of these cylinders there is an inverted cone, with a pipe passing through the ceiling and roof, and protected on the outside by a wind-guard, which allows the hot air and products of combustion to escape. By this contrivance the gas is consumed in a very heated atmosphere, and thus there is less necessity for combustion in order to obtain a given amount of light; for, in the generality of cases, a large portion of the gas consumed is employed in raising the air to the temperature necessary for sustaining the ignition of the small particles of carbon contained in the flame. It has been stated by Mr. Edwards, of Liverpool, that the burners, in this position, do not consume more than half the usual amount of gas; besides which, the intensity of the light is very great.

9. *The Common Argand Burner* produces a flame which is exactly like that of an ordinary Argand oil-lamp. The burner consists of a circular disc of iron, pierced with a number of holes. It is hollow in the middle, for the purpose of allowing a supply of air to the interior of the flame; and the jets of gas coalesce, so as to form a hollow cylindrical flame. A glass chimney is placed around the burner, in order that the supply of atmospheric air may be copious and steady. The number of holes or jets varies from ten to thirty for ordinary gas, and from thirty to ninety for cannel. In the former case the holes are comparatively large, and in the latter they are very small. When common gas is consumed from an Argand burner, the chimney ought not to be above seven inches in height; but, when cannel gas is burnt, it may be increased to nine or ten inches. If the chimney be too high, the supply of atmospheric air is too great, and the gas is overburnt; whereas, if it be too low, the supply is not sufficient, and then the gas smokes: in either case the intensity of the light is diminished. For ordinary London gas, a burner with fifteen holes, and a seven-inch chimney, is considered to be the best. Such a burner will consume about five cubic feet of gas per hour, and will give the light of fifteen sperm candles.

Several patents have been taken out, during the last few years, for improvements in this form of burner: they have chiefly been directed to the lessening of the shadow which is cast by the ring and body of the apparatus.

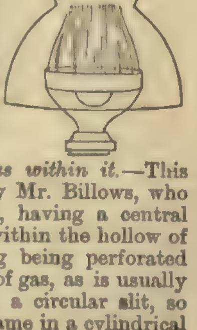
10. *The Argand with a Button or Deflecting Disc.*—This form of burner has received various names, according as it has been modified by different patentees. It is called the Winfield burner, Young's burner, Guize's burner, and the Aberdeen burner. The button or disc is composed of copper or iron, and it is placed in the centre of the flame, a little above the level of the burner. It acts as a break to the inner current of air, and deflects it outwards so as to enlarge the upper part of the flame, and to give it the form of a tulip (Fig. 130). This kind of burner is only suited for the richer kinds of gas, as cannel gas and naphthalised gas. In some cases the air is deflected to the outside as well as inside of the flame. This is the principle of Guize's burner, and the deflection is effected below the button by means of a bend or constriction in the glass chimney, or else by the aid of a metal cone like that of the solar lamp. In Young's burner there is a series of discs placed one above the other, the discs being successively larger and larger from below upwards; by this means the air suffers a series of deflections, and causes the flame to be most vivid. A burner of this description is particularly well suited for the combustion of very rich cannel gas.

Fig. 130.



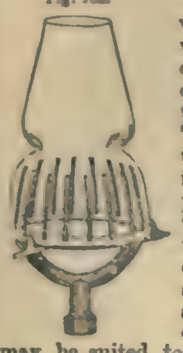
11. *The Argand Burner with two or more Rings of Flame, one within the other.*—This is the principle of the Boccius burner; and, from the circumstance that one flame always assists in promoting the combustion of another, the light from this burner is very considerable. Mr. Carter has obtained a patent for a burner of this description, modified somewhat in its form, so as to provide for a due supply of atmospheric air, and also to carry off the products of combustion. The burner consists of a series of Argand flames concentric to each other, with only just so much space between the rings as will serve for the transmission of the necessary quantity of atmospheric air; and over the flames there is placed a conical chimney, which carries away the products of combustion. In the concentric burners hitherto used, the object has been simply to obtain the effect of two or more concentric flames, without having due regard to the proper and uniform supply of air to each flame. The consequence of this is, that great and unnecessary quantities of air enter such burners; and the flame is thereby cooled much below the temperature requisite for the perfect combustion of the gas. On this account the intensity of the light is very much below what it ought to be. In Mr. Carter's burners this objection is overcome; for the space between the rings is properly graduated, and the current of air is made to compress the flame, and blow in upon it by means of a contraction in the glass chimney—the point of contraction being at such a height above the burner as to produce a bright and steady flame (Fig. 131). The ventilating-shaft is placed over the burner, and communicates above the ceiling with the chimney. It consists of a funnel, and a tube, which may be either of metal or glass. These are arranged so as to regulate the supply of air to the flames, and they are enclosed in a chandelier of glass pendants.

Fig. 131.



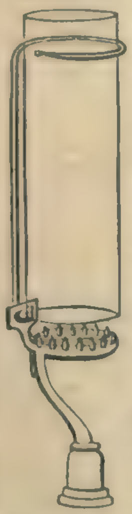
12. *An Argand with a Jet of Gas within it.*—This form of burner has been patented by Mr. Billows, who describes it as an ordinary Argand, having a central tube with a single jet, which burns within the hollow of the flame: and, instead of the ring being perforated with a number of holes for the issue of gas, as is usually the case, the ring is contrived with a circular slit, so that there is a continuous sheet of flame in a cylindrical form.

Fig. 132.



13. *Leslie's Argand* is the very reverse of the last; for the principle on which it is constructed is to allow a current of air to pass up between each of the jets, and so to destroy, to a certain extent, the continuity of the flame. This is effected by a number of small tubes, which rise to the height of an inch or so above the ring which supports them. These tubes are made to converge a little as they advance upwards, and thus they form a truncated cone (Fig. 132). The glasses are constricted, so as to deflect the air into the flame; and they are of different heights, in order that they may be suited to different amounts of consumption. These burners are very well suited for the combustion of cannel gas, but they destroy the light of common gas by overburning it. The flame should be always managed so as to reach nearly to the top of the glass: for if it pass above it, soot will be deposited; and if it do not reach almost to the level of the glass, the gas will be overburnt, and light sacrificed.

Fig. 133.



14. *The Pinnacle Burner*, of Messrs. Baldwin and Neal, is constructed on somewhat the same principle as the last, only the tubes are very short: they are, in fact, but mere nipples on the top of the ring, and the glass is not constricted (Fig. 133).

Many other varieties of gas-burners have been invented; and as the orifices of the jets are very liable to corrosion from the ammonia and sulphur contained in the gas, Mr. Hallen has proposed that clay or porcelain nozzles should be employed.

The relative value of the several kinds of burners, as employed in the combustion of ordinary London gas, as well as that from cannel coal, may be perceived from the following table. The value is represented as per cubic foot, in sperm candles of 120 grains consumption:—

Burner.	Cannel gas: candles per foot.	Common gas: candles per foot.
Single jet . . .	2·6 . .	1·5
Cockspur . . .	3·0 . .	1·5
Fish-tail, No. 1 .	3·0 . .	1·9
,, No. 2 .	3·6 . .	2·0
,, No. 3 .	4·0 . .	2·3
,, No. 4 .	4·3 . .	2·4
Bat's-wing, nearly the same as fish-tail.		
Leslie, with 28 tubes	3·6 . .	2·7
Gaumont . . .	4·0 . .	2·3
Common Argand 15 holes	4·0 . .	2·8
Bynner's 28 ,,	4·0 . .	3·2
Platow's 16 ,,	4·2 . .	2·9
Guize 26 ,,	4·2 . .	3·0
Winfield 58 ,,	4·3 . .	2·8
Billows', with 3 slits .	4·1 . .	2·6

From this it will be seen, that the simple jet is the worst kind of burner that can be used for the consumption of gas; next come the smaller-sized fish-tails, then the bat-wings, and lastly the Argands. The Gaumont or double fish-tail, and the Billows' or compound bat's-wing, are also very good burners. But it will be evident from the preceding table, that the burner which is best suited for common gas, is not always the one that can be most economically employed for cannel.

The pressure at which gas ought to be consumed is another point of considerable importance: for if the amount of pressure be high, the gas will burn with a roaring noise, and will be consumed wastefully; whereas if it be low, the fish-tail and bat's-wing flames will not be sufficiently spread out, and the light will be dim and smoky. Dr. Letheby states, in his Ninth Report to the Corporation of London, that gas ought to be delivered to the public at not less than half an inch of water pressure; and it may be said that, in practice, this is found to be the best pressure at which gas can be consumed.

Again, it is a matter of importance that the pressure at which the gas is supplied to the burner should be as uniform as possible; for if at one time the pressure be great, and at another low, the burner will require constant attention, in order that the flame shall be of one uniform height.

Experiments have been made to determine the rate at which gas burns under different pressures; and as the results are somewhat important, they are tabulated below. In a general way, it may be said, that by doubling the amount of pressure, we increase the consumption of gas by about half.

Burner.	Pressure in inch of water.	Consumption per hour.
Single jet . .	0·30 . .	2·6 cubic feet.

Dr. Fyfe has also observed, that there are certain constant relations between *the specific gravity* of a gas (that is, equivalent to its goodness) and *the pressure* at which it is burnt, and *the time* required to consume it—that is, provided we use a jet of a given size, and take care that the flame is of a given height. The jet which he prefers, is one having a hole the fortieth of an inch in diameter; and the height of the flame should be five inches. These relations are as follow:—

1st. The consumption of gas in a given time is as the square root of the pressure; and, consequently, the time required for the consumption of equal volumes, is inversely as the square root of the pressures.

2nd. The specific gravity of the gas is also inversely as the square root of the pressures.

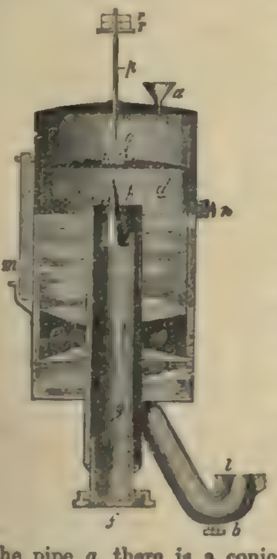
So that if we determine, by experiment, what time it takes for a given volume of gas, of known specific gravity, to burn from a jet of the given size, with a flame of the given height, we are then in a condition to tell the specific gravity, or the rate of consumption, of any other gas, provided it be burnt under the same circumstances, and we observe the pressure. This will be manifest from the following table:—

Pressure in inch of water.	Consumption per hour.	Specific gravity.
0·6 . . .	0·67 . . .	·841
0·7 . . .	0·72 . . .	·779
0·8 . . .	0·77 . . .	·729
0·9 . . .	0·81 . . .	·687
1·0 . . .	0·86 . . .	·652
1·1 . . .	0·90 . . .	·622
1·2 . . .	0·94 . . .	·595
1·3 . . .	0·98 . . .	·572
1·4 . . .	1·02 . . .	·551
1·5 . . .	1·05 . . .	·532
1·6 . . .	1·09 . . .	·515
1·7 . . .	1·12 . . .	·500
1·8 . . .	1·15 . . .	·486
1·9 . . .	1·18 . . .	·472
2·0 . . .	1·21 . . .	·461

By means of this table, we are able to determine the rate at which gas is burning, or its specific gravity, by merely observing the pressure which is necessary to obtain a flame of the given height. In conducting the experiment, the pressure-gauge must of course be on the jet side of the tap. Dr. Fyfe suggests that we may, by operating in this manner, do away with the necessity for a meter or a photometer, or both, and that we may arrive at results which are approximately correct. Of course it must be understood that the gas is of the usual quality, free from carbonic acid and atmospheric air.

When coal gas is supplied to the consumer at pressures which are variable, or inconveniently large, the difficulty may be overcome by using instruments which are called *governors* or *regulators*. In some small towns, the only means that are adopted for regulating the pressure of gas, is that of taking off or putting on the weights of the gasometer. But as this is a very inconvenient, and at the same time ineffective mode of regulating the supply of gas, it is usual, in all large manufactories, to employ a governor at the works themselves. This is a small gasometer, working very easily and truly in a tank or cistern of water. It is furnished with two pipes—one for the inlet of the gas, and the other for the outlet. The former is situated in the centre of the apparatus; and it is provided with a conical or parabolic valve. This consists of a conical or parabolic cavity or socket, in which a solid plug of the same form fits very accurately. The plug is attached to the top of the gasometer, and the inlet-pipe, containing the socket, is fixed to the bottom of the instrument: consequently, as the gasholder rises and falls, it carries the plug with it, and so opens and shuts the conical valve; by which means the supply of gas is regulated. Any amount of pressure short of that at which the gas is received into the apparatus, may be communicated to the delivery-pipe by means of weights that are put upon the top of the gasholder; and, as the governor is always placed between the large gasometer at the works, and the pipes constituting the street mains, the pressure of the gas in the latter is regulated in a tolerably effective manner. It would be very effective, indeed, if it were not that there is a rapid taking-off of pressure from the gas in the mains by the turning-on of the consumers' lights. This causes such a sudden and enormous abstraction of gas from the mains that the pressure immediately falls. For example:—In the early part of the evening, just before the lights of the neighbouring shops are turned on, the gas in the mains has a pressure of from one inch to one inch and a-half of water; but as soon as the supply is opened to the several burners of the locality, the pressure immediately drops to less than half an inch of water; and then again, when the lights are in great part turned off, the pressure quickly rises. This occasions much inconvenience to those who are burning gas in an economical manner; for it demands constant attention to keep the flame at its proper level. To remedy this, a smaller kind of governor is often used by the consumer himself. There are various forms of this instrument, but they are nearly always constructed on the same principle as the large one. They contain a valvular aperture, which opens or shuts according to the supply of the burners. This is effected either by the plug and socket already described, or by means of a disc which rises and falls over a small aperture. The first mode of constructing the governor was patented by Mr. Clegg, as long ago as the year 1815, and it constitutes the principle of most of the wet governors of the present time. Of these, one of the simplest in its construction is that manufactured by Mr. Glover. It is represented in Fig. 134. *f* is the connection by which it is fixed to the meter, and the gas passes through the pipe *g* into the gasometer *d*. At the top of the pipe *g*, there is a conical valve *i*, *h*, the plug of which is fixed to the top of the little gasometer *d*; and, consequently, as the gas enters the latter and lifts it out of the water in which it floats, the valve is closed. *p q* is a rod fixed to the top of the gasometer, and projecting beyond the cover of the instrument; it serves for holding weights, *r r*, which press down the gasometer, and communicate any amount of pressure that may be required. The gas escapes from *d*, through the outlet pipe *l*—water is poured into the apparatus through the funnel *a*, and it is kept at a proper level by the tube and plug *n*, while the gauge *m* enables the observer to note at what height the level of the water stands. Lastly, there is a plug at *b* to draw off any water which may happen to pass over or condense in the outlet pipe *l*. When the gas enters the chamber *d*, it lifts the gasometer, and with it the plug *h*, so that the aperture *i* is then closed. Directly the gas is let out from the chamber to the burners by the delivery tube *l*, the weights *r r* on the rod *p* immediately depress the gasometer, and then the valve is again opened for the entry of more gas; and thus, according to the weights at *r r*, and the supply to the burners, will the gasometer be rising or falling, and so will keep up a uniform supply and pressure.

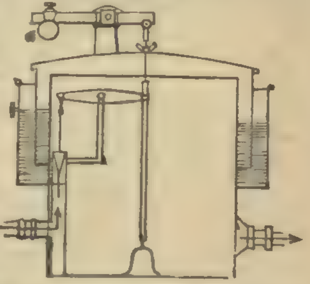
Fig. 134.



In the governor which has been constructed by Mr. King of Liverpool, the gasometer is made rather heavy, and it is suspended to one arm of a very nicely moving beam, like that of a pair of scales, while weights are attached to the other arm so as to regulate the degree of pressure.

In Mutrel's governor the beam is within the body of the instrument (Fig. 135), and the gasometer floats in an exterior vessel or chamber of water, while the pressure is regulated by a weight *a*, which slides backwards and forwards on an external beam.

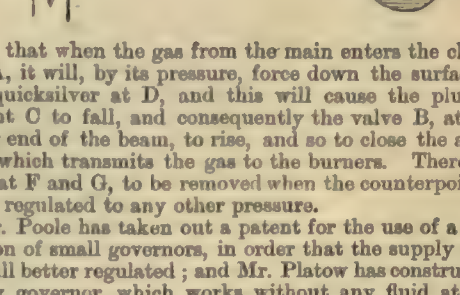
Fig. 135.



The American regulator, invented by Dr. Kidders, is constructed on the same principle, though the gasometer floats in quicksilver instead of water, and the valve is discoid in lieu of being conical.

The governor which is patented by Messrs. Hulett and Paddon contains the beam within a horizontal tube, and the weight floats upon the surface of quicksilver, so that the pressure of the gas may be made to regulate itself. This instrument is shown in Fig. 136. It will be seen, that when the gas from the main enters the chamber A, it will, by its pressure, force down the surface of the quicksilver at D, and this will cause the plug or weight C to fall, and consequently the valve B, at the other end of the beam, to rise, and so to close the aperture which transmits the gas to the burners. There are caps at F and G, to be removed when the counterpoise is to be regulated to any other pressure.

Fig. 136.



Mr. Poole has taken out a patent for the use of a succession of small governors, in order that the supply may be still better regulated; and Mr. Platow has constructed a dry governor, which works without any fluid at all. Lastly, Mr. Biddel has contrived a burner which regulates itself. It consists of an ordinary Argand, with a compound bar of brass and iron. The bar is formed of a brass tube with a central rod of iron; the latter is attached to the top of the former, and plays freely within it. When the burner is lighted, the bar stands up in the middle or hollow of the flame; and as these metals expand unequally for the same temperature, the motion of the longer rod is communicated to a small lever so as to move a plug which opens or shuts the aperture that delivers the gas. The temperature of the flame is thus made available as a means of regulating the supply of gas, and so of keeping the flame at one uniform height. After the burner has been once set, so as to produce the necessary amount of light, any increase in the supply of gas will immediately increase the size of the flame, and this will cause the bar to expand and act on the plug so as to shut off a portion of the gas. On the contrary, if the supply is not sufficient, the bar contracts, and then the aperture is opened.

ON THE GENERAL MANAGEMENT OF GAS, VENTILATION, Etc.

General Management of Gas.—On the continent, the government or municipal authorities enforce certain regulations for the management and distribution of gas. In Hamburg, for instance, the gas-fitters are obliged to perform their work in a certain manner: they must use tubes of wrought iron, brass, or copper; and in cases where these are not very easily adapted, tubes of drawn-tin may be employed. The joinings must be made in a durable and solid manner, either by means of sockets ground in and cemented with iron cement, or by screwing up, or by soldering. Any other mode of connection is forbidden. The tubes must be placed in localities where they are accessible, so that in case of leakage the mischief may be easily remedied. The cocks must be arranged in such a manner that they only make the fourth part of a turn, and they must be fixed so as not to be removable from the barrel. The gas-meters are to be furnished by the gas company, and examined and stamped by the adjusting commissioner. All the tubes of one inch or more in diameter must have a stopcock, so that they may be shut off from the main-pipe, in case of fire. No one is allowed to make use of his gas-fittings until the gas-fitter has tested their soundness, by means of a pressure of one inch of mercury or fourteen inches of water. All the gas-fitters are sworn to adhere to these instructions; and in case of any damage resulting from negligence on the part of the fitter, private persons are entitled to enforce their claims against him before a civil court of justice.

In a supplemental notice attached to the contract made between the English Gas Company in Paris and its consumers, the following regulations are recommended:—"To prevent any inconvenience in the use of gas, it is requisite that the burners should not allow any gas to escape in an unconsumed or imperfectly-consumed state. This result is obtained by maintaining the flame at a moderate height—three inches and a quarter at most, and confining it within a glass chimney of eight inches in height. The rooms lighted should be carefully ventilated, even during the cessation of lighting, by openings in the ceiling, through which the gas and its burnt products may escape. The plugs of the cocks should be greased from time to time, so as to prevent oxydation, and to facilitate their working.

"In *lighting* the gas, it is essential to open, in the first instance, the main-cock, and then to apply the light successively to each burner at the moment of opening its cock, so as to prevent the escape of any unconsumed gas.

"In *extinguishing the light*, it is better first to close the main-cock, and then to shut off the taps at each of the burners. Whenever a smell of gas indicates that there is a leak in the pipes, the doors and windows should be opened, so as to cause a current of air through the room; and the main-tap should be closed. The consumer should abstain from searching for any leak with a light, but he should rather give notice to the company and the gas-fitter. In case, whether by imprudence or by accident, the escape shall have been ignited, the best means of extinguishing it is to cover the aperture with a wet cloth."

These rules are of great importance, for very serious accidents have resulted from the explosion of gas mixed with atmospheric air. A few years ago—namely, in the month of August, 1848—a fearful disaster of this description occurred in Albany-street. The gas accumulated in the shop for a very short time only—in fact, it had been escaping no longer than one hour and twenty minutes from a crack in the meter; the area of the room was about 1,620 cubic feet; but when the gaseous mixture ignited, it blew out the entire front of the premises, carrying two persons through a window into a back-yard, and forcing another, by the violence of the shock, on to the pavement on the opposite side of the street, where she was picked up dead. For more than a quarter of a mile, on each side of the house, the effects of the explosion were severely felt, and the glass in most of the windows of the neighbourhood was shattered. But the most extraordinary evidence of its enormous power was exhibited in the condition of the premises which immediately faced the house that was destroyed: in one of these the iron railings around the area were snapped asunder, and in another a part of the roof and back windows were carried to a distance of from 200 to 300 yards; besides which, the pavement was torn up for a considerable length. According to the official reports which were made to the insurance offices, it appears that 103 houses were injured by the explosion, and that the damage done amounted to £20,000.

Another accident, of a similar kind, occurred in the month of July, 1850, at the Ilford toll-gate, whereby three persons were severely injured. The space in which the gas accumulated had an area of eighty cubic feet, and the gas had been escaping into it at the rate of forty cubic feet an hour for a period of fifteen minutes. A piece of lighted paper was incautiously introduced for the purpose of seeing where the leak was, and the mixture immediately exploded, breaking up the flooring of the room, blowing out the window, and knocking down a large portion of the front and partition walls of the building. These accidents were made the subject of scientific investigation, and reports were furnished to the journals by Dr. Arnott, Dr. Letheby, and Dr. Alfred Taylor. In speaking of the latter, Dr. Letheby says—"It is difficult to form an estimate of the total explosive force exerted by the gas on this occasion; but I am led to think that it was probably equal to about twenty tons; for when a column of mixed gas, consisting of one part of coal gas and seven of air (the proportion in this case), is fired, it expands to about five times its bulk, and exerts a pressure of about four pounds on the square inch." In the report given by Dr. Arnott on the explosion in Albany-street, it is stated, that the strongest explosive mixture consists of one part gas and ten atmospheric air, the expansion being in that case tenfold; and in a report furnished by M. Tourdes on the explosion which took place at Strasburg in 1848, it is stated, that the greatest force results from a mixture of one part of gas and eleven of air. These discrepancies doubtless arise from the variations in the composition of coal gas; but it may be stated, in a general way, that from seven to eleven parts of air to one of gas constitute the most dangerous proportions; for if the gas or the air be much in excess over these, the force of the explosion will be very much diminished. This is exemplified in a very striking manner by the admirable researches of Sir Humphry Davy into the explosive properties of light carburetted hydrogen, or *fire-damp*; for they show, that while seven or eight parts of air to one of gas produce the greatest explosive effect, other proportions are less dangerous: in fact, a mixture of equal parts of gas and air will burn, but it will not explode. The same is the case with a mixture of two of air, or even three of air, and one of gas; whereas four of air and one of gas begin to show an explosive tendency; and this becomes more and more marked up to seven or eight of air to one of gas. His experiments also prove, that one part of gas to ten, eleven, twelve, thirteen, or fourteen of air were also inflamed, but the violence of the combustion became less and less; and when the mixture consisted of fifteen parts of air to one of gas, there was no explosion at all.

These results indicate, that the most easy way of destroying the inflammability of coal gas, is that of mixing it with a large proportion of atmospheric air; and hence the necessity for good and effective ventilation wherever there is an escape of gas. We can recognise the odour of gas long before the mixture acquires explosive properties. Dr. Alfred Taylor states, that the smell of gas is perceptible when it is mixed with five hundred parts of atmospheric air; and that it is very manifest when it forms one part in a hundred and fifty of air. We have, therefore, a ready means of discovering the danger; and, indeed, the offensive odour of coal gas is one of its most valuable properties; for if it were to be deprived entirely of its odour, accidents would be far more frequent than they are at present.

As gas is lighter than atmospheric air, it is always disposed to accumulate in the upper part of the room; and here it is that ventilation will be most effective. Still, however, there is a strong diffusive power possessed by all gases, by virtue of which they rapidly commingle; and hence the necessity for a complete displacement of all the atmosphere of a room in which coal gas has been escaping.

Dr. Taylor attaches importance to the poisonous properties of coal gas; saying that there are reports of six deaths on record, where persons have been killed by sleeping in rooms near to which there was a leakage of gas. M. Tourdes found, that an atmosphere containing one-thirtieth, or even one-fiftieth, part of coal gas seriously affected animals. It cannot, therefore, be too strongly impressed upon the minds of those who use gas in dwelling-houses, that where a smell is perceptible, the defect should be immediately found out and remedied. When the leakage is comparatively slight it may endanger the lives of those who sleep in or near the spot; and when it has reached a higher point, it may lead to a serious accident by explosion. The effects which it produces on the human system are those of depression, headache, sickness, and general prostration of the vital powers, followed by deep coma.

Gas Ventilation.—It has been already stated that the products of gas combustion are very pernicious—that they not only cause discomfort to the feelings, and perhaps injury to the health of those who inhale them, but they are also very destructive to property; besides which, the high temperature which is produced in rooms where gas is burnt in a wasteful manner, is very objectionable. All these circumstances render it necessary that the products of combustion, as well as the heated atmosphere, should be removed as speedily as possible. In fact, it is of the greatest importance that gas should be consumed in such a manner as not to affect the atmosphere of the room at all. Several contrivances have been suggested for the purpose of effecting this.

Many years ago, when the books in the library of the Athenæum Club-house were found to have been impaired by the gas used in the building, Professor Faraday invented an apparatus which was found to remedy the evil. It consists of an ordinary bat's-wing, or fish-tail burner, enclosed in a globe or bell-glass, closed at the top with mica; the interior of the globe communicates with a tube, which surrounds the gas-fitting, and passes away through a condensing cistern to a ventilating shaft. The tubes are so arranged as not to be visible, and the burners are suspended in the ordinary way from a chandelier. By this contrivance the gas burns in a closed chamber, and the products of combustion are at once carried away. This plan of consuming gas is practised at the club-house before mentioned, and also at Buckingham and Windsor palaces; but the great objection to it is the frequent breaking of the glasses, and the necessity for a ventilating shaft with a strong upward current.

The *sun-burner* has already been described, and so also has the ventilating burner of Mr. Carter.* Messrs. Whichcord and Rosser have also patented a contrivance for effecting the same purpose; it consists of a ventilating-bell and draught-tube placed over the burner. If the bell is lowered so as to be a little below the level of the glass chimney, and the whole surrounded by a glass globe which is open only at the top, a current of atmospheric air passes down over the tube and chimney, and thence to the flame, where it is consumed, after which it passes away through the draught-tube. By this means the air is heated before it reaches the flame, and therefore the intensity of light is augmented; besides which, the cooling influence of the air on the draught-tube and chimney prevents the heat of the gas from being communicated to the room.

Another mode of effecting ventilation, is to place a simple catch-tube, or funnel, over the gas, and thus to carry away the products of combustion into a neighbouring chimney, or to the outside of the house. The draught-tube need not be very large, and it may be hidden above the ceiling. When this plan is not available, a less perfect mode of ventilation may be adopted by boring a number of holes through the ceiling immediately over the chandelier or burner. The holes should be about half an inch in diameter, and they should communicate with the space above the ceiling. A few ventilating bricks should also be introduced into the wall, bounding the space on each side of the house, so as to carry off the warm air. The holes in the ceiling may be hidden from view by means of a perforated or open rosette.

Lastly, where gas can be burnt out of the room altogether, it is of the greatest importance that no plan of internal combustion should be adopted. Shop-windows, for example, are best lighted by means of an external jet with a reflector. On the continent this is the plan very generally employed; and it is found to produce a much more pleasing effect, than when the burners are placed on the inside of the windows. There is no reason why gas may not be used in a somewhat similar way for illuminating private rooms. At present we generally receive the light from the ceiling, and the combustion takes place in the atmosphere of the room; but it is quite possible to burn the gas in a closed chamber at the side of the room; say, for instance, in a recess which might be formed by removing a portion of the wall in some convenient situation, as between two windows. This recess might have a number of small gas-burners with reflectors behind them; and it might be covered in front with ground glass, ornamented with some device. It should, of course, communicate with the external atmosphere, and be shut off from the room. By day it might be covered by a mirror; and at night the mirror might be slid to one side, so as to form a shutter for a window. Again, in some situations where the space between the ceiling and the upper floor is very considerable, a ring of gas jets, or a sun-burner, might be introduced into a closed chamber in the ceiling, and the light might be reflected or diffused in a very agreeable manner. In short, there are many plans which might be suggested for a more perfect and wholesome mode of burning gas for illuminating purposes than that which we generally employ; and there is no doubt that if attention were sufficiently aroused to the importance of this subject, many improvements would be adopted.

Vitiating Effects of Illuminating Agents.—Although gas is generally regarded as the most injurious of all light-giving bodies, yet this is not true when we consume it in moderation; that is, when we burn it in such a manner as to obtain the same amount of light as we are accustomed to have from other agents. This will be made evident from what follows. A very little consideration will show that we have become exceedingly wasteful in the use of gas, burning it in situations where we obtain the least possible advantage from its luminous effects, and demanding such a strong glare from it, that there is a much larger consumption of the material than need be; and consequently there is a larger vitiation of the atmosphere than would occur with any other illuminating agent. Take the case of an ordinary sitting-room. With two candles on the table, at a distance of a foot from the observer, he can see well enough to read, write, or work. But suppose that gas is introduced into the room: it is placed in a chandelier four or five feet from the table, and then, according to the law of intensity, it requires twenty-five candles' worth of light to give the same amount of luminosity on the table; and so two or three gas-burners, consuming in all about ten cubic feet of gas per hour, are fitted up to do the work of two candles. It is this profusion of light and heat which has occasioned so strong a prejudice against the employment of gas, on the score of its heating and vitiating effects; but the prejudice is not well-founded. Dr. Frankland has made experiments to determine the relative amounts of carbonic acid produced by the usual illuminating agents, and he states that the following proportions of carbonic acid are produced per hour during the combustion of a sufficient quantity of each of the materials to get the light of twenty sperm candles, each burning at the rate of one hundred and twenty grains per hour:—

---

* See *ante*, p. 129; Fig. 131.

Tallow	10·1 cubic feet.
Wax	8·3 ,, ,,
Spermaceti	8·3 ,, ,,
Sperm oil	6·4 ,, ,,
Common London gas . .	5·0 ,, ,,
Manchester gas . . .	4·0 ,, ,,
London cannel gas . .	3·0 ,, ,,
Hydro-carbon Boghead gas	2·6 ,, ,,
Hydro-carbon Lesmahago gas	2·3 ,, ,,

Now, if we bear in mind that each cubic foot of carbonic acid involves the destruction of nearly five cubic feet of air, and that, according to toxicologists, a proportion of five per cent. of carbonic acid in the atmosphere is dangerous to animal life, we shall perceive that there is an enormous amount of atmospheric air vitiated and rendered irrespirable from this cause alone; but to this must likewise be added an almost equally large quantity of oxygen which is consumed by the hydrogen of these illuminating agents, and which in coal gas amounts in many cases to nearly fifty per cent. It will be manifest, therefore, that in obtaining artificial light by any of these means, we destroy a large quantity of atmospheric air; and hence provision should be made for an ample supply of it by means of good ventilation. This will be still more evident from what follows.

Mr. Lewis Thompson has instituted a set of experiments for the purpose of ascertaining how long a flame of a given intensity, obtained from different illuminating agents, will burn in a given bulk of atmospheric air. In all cases the value of the light emitted was the same—namely, that of thirteen standard sperm candles, each of one hundred and twenty grains' consumption per hour; and a distinct experiment was made with each agent. The times that elapsed before the flames were extinguished were as follows:—

Rape or Colza oil . . .	71 minutes.
Olive oil	72 ,,
Russian tallow . . .	75 ,,
Town tallow	76 ,,
Sperm oil	76 ,,
Stearic acid	77 ,,
Wax candles	79 ,,
Spermaceti candles . . .	83 ,,
Common coal gas . . .	98 ,,
Cannel coal gas . . .	152 ,,

These times are inversely as the salubrity of the illuminating agent; and hence it follows that common rape oil is the most destructive of the atmosphere, and rich cannel gas the least.

The same is true of the heating effects of these bodies. Already we have alluded to this fact; but as it has been made the subject of special experiment by Mr. Lewis Thompson, we will again refer to it. He says, that when the following materials are burnt for an hour, in such quantity as to give the light of one sperm candle of one hundred and twenty grains' consumption, they raised the following amounts of water from the temperature of 60° to 212° Fah.:—

Cannel gas	raised	4074	grains	of water	152°
Common gas	,,	6840	,,	,,	,,
Sperm candle	,,	7505	,,	,,	,,
Tallow candle	,,	7534	,,	,,	,,
Colza oil	,,	7870	,,	,,	,,

"The impossibility of maintaining one uniform rate of consumption in the case of the candle and oil, detracts slightly from the value of the results; but the indications are too decisive to permit the general conclusion to be doubted—that, light for light, the inconvenience arising from heat is much less with gas than with any of the ordinary agents employed to give light; and in the case of cannel gas the advantage is very great."

ILLUMINATING AGENTS WHICH DO NOT VITIATE THE ATMOSPHERE.

Of these there are two which are especially deserving of notice: they are the oxy-hydrogen, or Drummond light, and the electric light.

The Oxy-hydrogen Light.—This was first introduced to public notice by Lieutenant Drummond. It consists of a jet of oxygen and hydrogen gases, or of alcohol and oxygen, burning so as to ignite a piece of lime or magnesia; and the high temperature which is thus produced, renders the earthy body so incandescent as to be intensely luminous.

The apparatus which is employed for the production of this light has, at various times, undergone considerable alteration and improvement. Originally the mixed gases, consisting of two parts, by measure, of hydrogen and one of oxygen, were condensed, by means of a syringe worked at great pressure, into a square metal box, from which there issued a long jet, of very small bore; this jet passed through a thick oak partition, in order that the operators might be protected from the danger which was incidental to the bursting of the metal box from explosion. This was the form of apparatus originally contrived by Clarke and Newman. After this the safety-jets of Gurney, Hemming, and others, were adopted; and at the present time, it is customary to burn the mixed gases by means of the latter, or else to deliver the gases separately into a double jet or nozzle, where they mix immediately before they are consumed. Both of these plans are very manageable, though the latter is thought to be less open to the risk of explosion than the former.

The hydrogen gas is obtained by acting on zinc with dilute sulphuric acid (one of acid to ten or twelve of water); and the oxygen, by heating a pulverulent mixture of four parts of chlorate of potash and one of peroxide of manganese in a glass retort. In each case the gas is to be collected in a gasometer, or else in bladders fixed to receivers over a pneumatic trough. Mr. Watson has obtained a patent for procuring the gases already mixed in proper portions by the decomposition of water by galvanic agency; but the process is an expensive one.

When the mixed gases are burnt, the flame is projected upon a small cylinder of lime or magnesia, which is from time to time turned round, so as to expose a fresh surface to the action of the flame.

Another mode of obtaining this light is to throw a jet of oxygen into a flame of spirit of wine or ether, or to mix the oxygen with coal gas instead of with hydrogen.

The light which is obtained by either of these plans is very intense. When concentrated by means of a concave mirror, it is distinctly visible at a distance of sixty-five miles; and when compared with the light of a wax candle, the mixture of oxygen and coal gas is equal to twenty-nine of such candles; that of alcohol and oxygen to sixty-nine; that of ether and oxygen to seventy-six; and that of hydrogen and oxygen to a hundred and fifty-three. In consequence of the great intensity of the oxy-hydrogen light, it is generally employed for the phantasmagoria, the dissolving views, and solar microscope, and for theatrical illuminations, and experiments in optics; besides which, it has been recommended for lighthouses and signal-lights. The light differs from all others which have been described, in the circumstance of its being exceedingly white, and therefore well suited for the display of bright and delicate colours. With this light the various shades and tints of a picture or dress are as plainly discernible as they are by the diffused light of day.

The Electric Light.—Within the last few years, public expectation has been raised to a great height, by the announcement that voltaic electricity might be made the means of producing a very pure and intense light; and several patents have been taken out for the purpose of accomplishing this. Indeed, many exhibitions of the light have been made at several public institutions, and also in the open air, by which the sanguine hopes of its originators have been apparently increased. Of late, however, little has been heard of the subject beyond the few remarks which occasionally fall from men of science in their discourse upon it.

The idea of employing electricity for this purpose is not novel; for the power of the voltaic light was thoroughly investigated in the time of Sir Humphry Davy; but the difficulties which electricians had then to contend with in the inconstancy of the galvanic battery, offered an insurmountable barrier to its use. A part of this difficulty was overcome by the late Professor Daniell, who was the first to contrive a constant battery. Since then, the voltaic arrangements, by which a current of electricity of great power may be sustained for any length of time, have been improved by Mr. Smee, Professor Grove, M. Bunsen, and the Rev. Professor Callen, of Maynooth; so that, at the present time, there are abundant facilities for producing the light.

The first patent which was taken out for the use of electricity for illuminating purposes, was that of Mr. Staite, in November, 1846. In July, 1848, he obtained another patent for an improved form of battery. This he called the *perfluent* battery, in contradistinction to the *percolating*, which was already in use. It was thus named on account of the arrangement which he adopted for keeping up a supply of acid. The troughs, or cells of the battery, communicated with each other by means of elastic syphons or cross tubes, and the acid was made to flow from cell to cell throughout the entire length of the series; so that, when it arrived at the last cell, it was completely exhausted of its exciting power, and saturated with zinc. It was thought that such an arrangement would be the means of economising power and material; but it happens to be the very worst that could possibly have been contrived for such a purpose. The electrician knows, that if he requires the greatest power from his battery, each of the cells must be acting alike, and to their fullest extent; for it is the condition of electricity to multiply itself, not after the ratio of the most powerful cell, but after that of the weakest. If, therefore, we have in the arrangement a number of cells working unequally, as is the case in the perfluent battery, the activity of the one set of cells will be of no avail in raising the inactivity of the other; for the least powerful cell governs all the others, and reduces them to its own standard. It follows, therefore, that the last cells in Staite's arrangement must act as clogs on the first; for, as they are almost without action, they must reduce the power of the first cells to little or nothing. Another alteration, proposed by Mr. Staite, was, that a liquid amalgamation of zinc and mercury should be used in bags, or porous cells, in lieu of the ordinary form of amalgamated zinc. He also suggested the use of a solid amalgam, consisting of 5 of zinc and 1 of mercury. He likewise proposed that lead should be employed instead of zinc, in order that valuable products might be obtained. All these suggestions, however, are of no value; for they are contrary to the principles on which a good galvanic battery ought to be constructed.

In July, 1848, the Chevalier Alexandre Edouard Lemolt also took out a patent for improvements in the batteries and apparatus used in obtaining the electric light. His improvements in the battery were but modifications of those long since adopted by Professor Bunsen. He employed plates of carbon, which were either cut out of the hard coke which lines the interior of gas retorts, or else formed by powdering the coke, mixing it with a little coal-tar, then pressing it into a mould, and baking it at a low red-heat. Since then—namely, in the month of February, 1849—Mr. Charles Thomas Pearce obtained another patent for improvements of a like description. His battery was a perfluent one, and it differed from Staite's in the circumstance that the flow took place separately in each cell, and not from cell to cell; so that the amount of power generated in each cell was the same, and his porous diaphragms were made of sycamore wood, soaked in dilute acid. Another of his claims was the use of alkaline salts in solution, which did away with the necessity for amalgamating the zinc. Lastly, another patent has since this been obtained by Messrs. Staite and Petrie, wherein they recommend a modification of their former arrangement, so as to keep the liquids in all the cells of the same degree of strength. Each of these patentees has likewise secured to himself the use of certain contrivances, whereby the charcoal-points which emit the light shall be removed and kept at a proper distance from each other. These, in fact, constitute the real claims to consideration; for the batteries which they have invented are not worthy of the least attention.

Batteries used in obtaining the Electric Light.—(*a.*) *Daniell's Battery*, which consists of a jar containing a cylinder of sheet copper, and a saturated solution of its sulphate; within this there is placed a porous cell (composed of brown paper, unglazed earthenware, or bladder), which holds a cylinder of sheet zinc, and dilute sulphuric acid. These are arranged so as to obtain both quantity and intensity of electricity.

(*b.*) *Grove's Battery* is constructed in a very different manner. The outer cell is of an oblong form, and it may be made of glass, earthenware, or gutta-percha. It contains a piece of sheet zinc bent into the form of the letter U, one leg being a little longer than the other. The zinc is amalgamated according to Mr. Smee's plan, by dipping it into dilute sulphuric acid, and then covering it with quicksilver. Within the bend of the zinc there is placed a porous oblong cell of unglazed earthenware, and within this a sheet of platinum. The battery is set in action by pouring dilute sulphuric acid (in the proportion of one acid to seven water) into the zinc compartment, and strong nitric acid into the platinum cell. As before, the battery may be arranged for quantity as well as intensity.

(*c.*) *Bunsen's Battery*, as well as that modification of it proposed by M. Lemolt, is truly a Grove's battery, with a piece of charcoal instead of a sheet of platinum.

(*d.*) *The Maynooth Battery*, which was contrived by the Rev. Professor Callen, of Maynooth, is also a modification of Grove's principle; for a plate of cast-iron is used instead of platinum; or a cast-iron cell is charged with a mixture of two parts of strong sulphuric acid, one-and-a-half of nitric acid, and the same of water; and it is better to excite the zinc with a strong solution of muriate of ammonia instead of with dilute sulphuric acid, for this does away with the necessity for amalgamating the metal.

Professor Grove says that the result of his experience is, that the nitric acid battery, in one or other of the preceding forms, is the only one, hitherto invented, which offers anything like a practical means of applying this power to illuminating purposes; and the best arrangement that can be adopted for obtaining the greatest amount of power, is to use about forty or sixty cells, arranged in two series of twenty or thirty each. By this means we have the quantity of two cells, and the intensity of twenty or thirty. If we go beyond this in the intensity arrangement, the fluids in the cells begin to boil, and quickly to evaporate. This is objectionable; for it not only renders the atmosphere of the room irrespirable, but it frequently brings the action of the battery to a standstill. The source of power in all cases is the chemical action which takes place in the cells.

Mode of obtaining the Light.—The wires which convey the electricity from each of the series must be connected, so that the two positive poles are brought together, and the two negatives. The wires should be of large size, so as to conduct the electricity with ease; and they should be covered with gutta-percha, so as to insulate them. If this precaution be not taken, they may touch each other, and so cut off the current; or they may become unmanageably hot; or they may communicate a shock to the operator. It is usual to have the galvanic batteries in any convenient place at a distance from the experimenter, and to convey the electricity, by means of the insulated wires, to the point where it is wanted. Light may be obtained from the battery in two ways: either by bringing the poles into contact with a yard or so of platinum or iridium wire, wound into the form of a spiral; or by terminating them with cylinders of charcoal, and then bringing them into contact. In each case the light is produced by the ignition of the conducting medium. Platinum or iridium is not so well suited for the purpose as charcoal, because, in the first place, the light is never so vivid, and, in the second place, the metal is very likely to fuse, and put a stop to the experiment. When charcoal is employed, it is found that the greatest intensity of light is produced by drawing the points apart to the extent of from a quarter to half an inch; and then there is a stream of finely-powdered charcoal, in a most intensely ignited state, projected from one pole to the other, forming an arc of flame. If the charcoal-points are too close together, we do not obtain the maximum effect; and if they are too far apart, the arc is broken, and the light extinguished. This it is which constitutes the difficulty in keeping up the electric light, and which gives to the flame its unsteady, flickering character. Consequently, all the contrivances which have been adopted for overcoming this, have been made the bases of the several patents to which we have alluded. These we shall now proceed to describe.

Fig. 137.

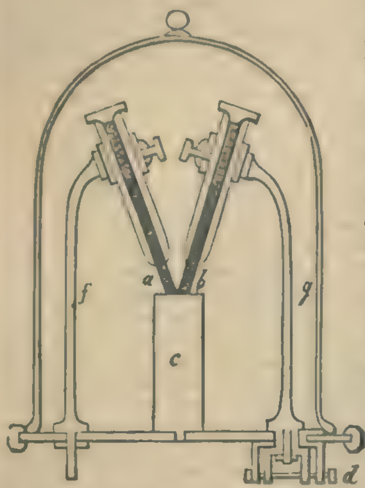


Fig. 138.

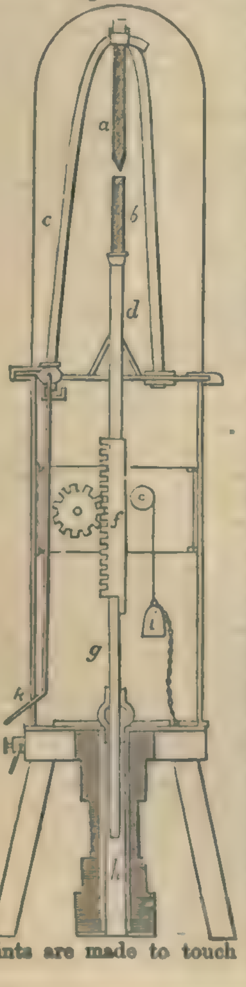
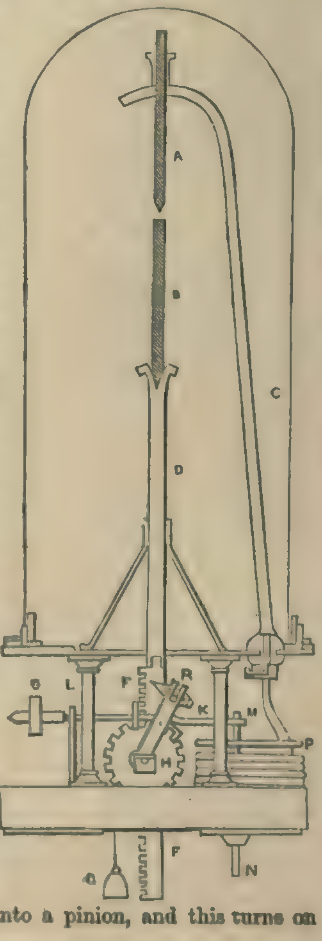


Apparatus for sustaining the Electric Light.—The first of Mr. Staite's patents was for a contrivance or method for maintaining the charcoal-points at a uniform distance. One of these is represented in Fig. 137: *a* and *b* are the charcoal-points; they slide easily in a brass tube which holds them, and their free ends rest upon a solid cylinder of plaster of Paris, *c*. At the opposite ends they are pressed upon by a spiral spring, which is contained within the brass tube; and by which means they are always forced down very firmly on the plaster of Paris cylinder. There is an adjusting screw at *d* for regulating the distance of the points, and the arms *f g* convey the current. To set it in action, the two charcoal-points are made to touch by means of the adjusting screw *d*, and then they are separated to the required distance, so as to get the maximum amount of light. As the points burn away, the springs keep up a fresh supply by forcing them down on the plaster of Paris cylinder, and maintaining them at their proper distance. It was at first thought that this arrangement would meet all the difficulties of the case; but it was soon found that there were irregularities in the action of the battery, as well as a projection of the charcoal from one pole to the other, which demanded a constant motion of the points; and, therefore, a few months afterwards the patentee adopted another invention, whereby the points were adjusted by the aid of an electro-magnet. A third patent, with still further improvements in this respect, was obtained in the course of the same year. In this last patent there are three distinct kinds of apparatus described for the management of the electric light—namely, one for obtaining a regularly intermitting light, another for procuring a constant and uniform light, and a third for developing a constant light by the ignition of a metallic wire.

The apparatus for producing the first effect is represented in Fig. 138: *a b* are the two charcoal-points; one of them is fixed to the conductor *c*, and the other to the movable rod *d*. The lower part of *d* is fixed to a rack *f*, and this to an iron rod *g*, which moves freely up and down in a tube *h*, that is surrounded by a coil of wire in the form of a helix: a weight *i* is attached to the rod *f g* by means of a string, which passes over a pulley. The object of this is to counterbalance the weight of the rod, rack, and charcoal-holder; and there is a small piece of chain also attached to the weight, so that the balance may be equalised as the rod is pulled down. The action of the apparatus is as follows:—The conductor *k*, and the wire of the helix around *h*, are brought into connection with the galvanic battery, and the circuit is closed by bringing the two charcoal-points into contact. At this moment the iron rod *g* is rendered magnetic, and is drawn down into the hollow tube within the helix. By this means the charcoal-points are separated, and a most intense light is produced; but soon the separation takes place too far, and then the circuit is broken and the light extinguished. The iron bar now loses its magnetism, and the weight draws it up again, so as to bring the charcoal-points once more into contact, when the same phenomenon is repeated. It is obvious that by this contrivance a succession of flashes at regular intervals is produced, and the weight may be so regulated as to maintain any period for the duration of the light and its intermission.

Fig. 139



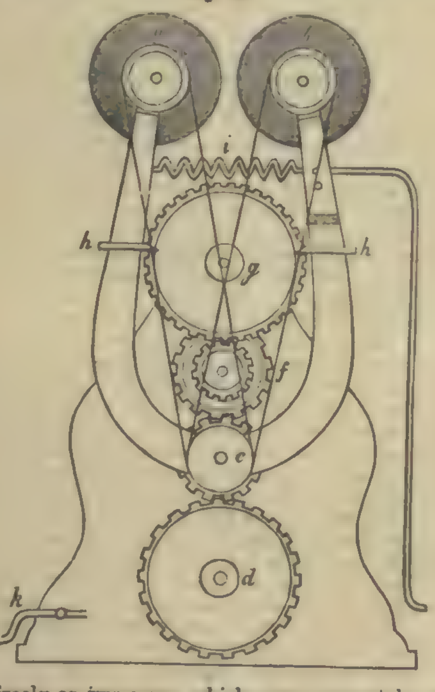
The apparatus for producing a constant and uniform light is shown in Fig. 139. The charcoal-points A B are attached as before—one to a fixed conductor C, and the other to a moveable conductor D; the latter is moved by a rack F F, which works into a pinion, and this turns on a spindle with fixed supports. A barrel is attached to the pinion, and over this there passes a string, to which the weight G is fastened: by this means the rod and rack D F are counterpoised. To the spindle there is fixed a cogged wheel H and a lever I; the latter carries a double paul, which locks into the cogs of the wheel in either direction. A long horizontal lever, K, passes over the paul, and moves on the fulcrum L; while it supports at one end a rod M, which is fixed to an iron bar N, and at the other a movable counterpoise O. The iron bar travels freely up and down in the coil P.

The paul and its lever I are kept in a state of slow vibration from side to side by means of a crank R, which works in a fork at the end of the lever I. This crank is made to revolve by an ordinary train of wheelwork, furnished with an escapement or fly-wheel, and driven by spring-power or by weights. The object of this movement is to elevate or depress the rack F by turning the wheel H.

The mode of action of the apparatus is as follows:—The negative pole of the battery is brought into contact with the rack and rod D, F, and the positive pole with the coil P, and thence with the upper charcoal support C. Immediately the points touch, and the circuit is completed, the coil raises the iron rod N. This acts on the lever K, and causes the lower charcoal-point to descend and separate from the upper one. Directly the separation has taken place to the maximum extent, there is a contrivance (not shown in the drawing) which arrests the movement of the rack, and so keeps the electrodes stationary. Before the apparatus is set to work, the proper distance for the charcoal-points is adjusted by means of the counterpoise O, which screws backwards or forwards on the short arm of the lever K, and thus regulates the movement of the rod M, N. If the light should go out, and the circuit be broken, the rod N immediately falls, pulling down with it the long end of the lever K. This presses upon one arm of the paul, and gives motion to the wheel H, whereby the rack is elevated, and the charcoal-points again brought into contact.

M. Lemolt's apparatus for adjusting the charcoal electrodes is somewhat different from the last. In the first place, the electrodes are not cylindrical, but are in the form of circular discs, *a*, *b*, Fig. 140; and they revolve freely on two arms, which move separately on one common axis, *c*. This axis also carries a pinion, the square cogs of which are in communication below with the driving-wheel *d*, and above with another pinion *f*, the inner cogs of which are in gear with a large wheel *g*. Over the drum of the pinion at *c*, there pass two endless pulleys, which give motion to the charcoal discs, *a*, *b*. In order that the discs may be at a proper distance for the production of a good light, there are two adjusting stops *h h*, fixed to the arms on which the discs rotate. These stops are brought into close contact with two cams, which are situated in the periphery of the wheel *g*; and as this wheel rotates, the charcoal discs are brought closer and closer together, so as to compensate for the wear of the electrodes. There is a spiral spring at *i* to keep the arms and their stops tight against the cams. The apparatus is thus set in motion—the terminal wires of the battery are brought into connection with the charcoal discs by means of the conductors *k*, *l*. The driving-wheel *d* is then set in motion by clockwork within the case of the instrument, and its motion is communicated to the other wheels, and also to the charcoal discs. The discs are then brought together so as to complete the circuit, and the stops are adjusted in the cams, so as to produce the necessary arc of flame. By the revolution of the discs, new surfaces are constantly presented to each other, and the old or worn edges are cleaned down by the sides of the stirrups in which they revolve.

Fig. 140.



In Mr. Pearce's arrangement, there is a prismatic or cylindrical bar-electrode in contact with one, two, or three of a discoid form. These are moved by clockwork; and it is so managed, that while the first advances or rises through its sheath, the others revolve at a proper distance from it, and the edges are kept clean by means of iridium cutters. The charcoal bar is also held by the iridium conductors, which grasp it close to the ignited point. The advantage of this mode of mounting the electrodes is, that if from any cause, such as unequal waste of carbon, or irregularity of surface, the light should be extinguished at one point, the others remain burning, until by the further revolution of the disc, or the advance of the bar, the electrodes are again brought into contact, and the light restored. Besides which, in presenting two or three centres of light, so merged as to appear as one in a reflector, there is greater brilliancy and greater steadiness of flame.

Another apparatus has been patented by Mr. Pearce, which does away with the necessity of clockwork altogether. It consists of two bar-electrodes, which are approximated by means of springs or weights and pulleys; and the necessary distance is preserved by the intervention of slips of non-conducting charcoal. He has also contrived a plan for relighting the electrodes in case the arc of flame is blown out. This he effects by aid of a wedge-shaped piece of charcoal, which falls down between the electrodes directly the light is extinguished, and thus re-establishes the contact. The charcoal is fixed at one end of a lever, and to the other end there is a soft iron armature: this is placed opposite to a soft iron magnet, enclosed in a coil which carries the current. While the electricity is passing, the electro-magnet draws the armature to it, and so keeps the wedge-shaped piece away from the electrodes; but directly contact is broken, the armature retires, and the wedge-shaped piece falls down between the poles and re-establishes the arc.

Mr. Staite has patented a plan for obtaining a constant and uniform light by the ignition of a loop of platinum or iridium wire, enclosed in a glass globe from which the air has been exhausted. But there is no novelty whatever in this contrivance; and, consequently, it is undeserving of further notice.

Some little attention is necessary to the quality of the electrodes, in order to get the best effect. *Common charcoal* is unsuited for the purpose, because of its being in most cases a non-conductor of electricity; the *charcoal of porous wood* is also objectionable, from the circumstance of its burning away very rapidly: therefore it is that electricians make choice of the densest varieties of carbon. One of these is the *charcoal from boxwood*, which is obtained by cutting the wood into pieces of nearly the required form: they are then put into a crucible, filled up with fine sand, so as to secure the exclusion of atmospheric air, and exposed for two or three hours to a bright red or white heat. The crucible is to be well covered, and allowed to cool before the charcoal is taken out.

Hard coke has been employed with considerable advantage by many persons. The objection to it is, that it frequently scintillates, from the large quantity of iron which is contained in it. This difficulty may be overcome by powdering the coke, then stirring it about with a magnet so as to attract the iron, or else digesting it in nitro-muriatic acid, and washing very well before drying. The powdered coke is then to be moistened with a little syrup or coal-tar, and rammed into a cylindrical mould: the bar which is thus made must be ignited in a crucible covered with sand, in the same way as that already described for the preparation of boxwood charcoal. These cylinders will be found exceedingly hard, and they give a light which is superior in whiteness and intensity to that from any other kind of charcoal. If the electrodes are soaked in a strong solution of common salt, and then dried, they give a still more brilliant effect; and by using a salt of copper, chloride of strontium, &c., we obtain green, red, and other coloured flames.

Again, it has been noticed that the intensity of the light is increased by removing the atmospheric air from the vessel containing the electrodes, and effecting contact in a rarefied atmosphere, or in a vacuum. The *effects* which are produced in this manner are very remarkable; for the purity and intensity of the light are greater than those from any other source. In the first place we find that it simulates the light of the sun, in the circumstance of its affording a means of distinguishing the most delicate tints of colour: blues, yellows, and whites, which are not to be seen in a pure state by ordinary artificial light, are recognisable by this mode of illumination as if they were seen by day. Again, when the light is decomposed by a prism, we obtain a spectrum which is similar to that afforded by the rays of the sun.

The intensity of the light has been variously estimated. That which was exhibited by Mr. Staite on the 30th of May, 1849, from the summit of one of the towers of the Hungerford Suspension-bridge, was said by him to be equal to 750 wax candles. Professor Grove, in experimenting with a battery of thirty cells, the platinum being four inches by two, obtained a light which equalled that of 1,444 wax candles; and Dr. Letheby states, that in some experiments which were made by Mr. Hearder, of Plymouth, in the month of April, 1849, with a Maynooth battery of eighty cells, each four inches square, arranged in two sets of forty each—the light, when concentrated by a parabolic mirror, and sent over the country for a space of 5,490 yards, gave a light equal to that of a candle at thirty feet distance; so that the intensity of the focussed light was equal to that of 301,401 candles. It is probable that Mr. Grove's estimate is nearest to the truth, as great pains were taken in his investigations to arrive at correct results.

It is very natural that a light of so great brilliancy should command a large share of public attention, and should likewise be made the subject of frequent experiment. Hence it is that Mr. Staite and others have often exhibited it in London and elsewhere. When it was shown from the top of the Hungerford Suspension-bridge, the light was sufficiently intense to illuminate the water-frontage of Somerset House; and when it was cast to the opposite side of the river, it lighted up all the buildings on the Surrey shore. Exhibitions of it have also been made at the Hanover-square Rooms, from the top of the Duke of York's Column, and from the portico of the National Gallery; but the most marvellous illustration of its power was afforded by Mr. Hearder, of Plymouth, who placed the light at the top of the Devonport Column, and first experimented with it at Trematon Castle, which is distant about 18,266 feet; and then at Bovisand, which is 16,470 feet from the column. At the former place the light was sufficiently strong to mark the time on the seconds-hand of a small watch, and the walks of the castle were distinctly visible at a distance of half a mile; besides which, the ivy-leaves over the gateway of the building were plainly seen when the observer was sixty feet away from them. Its intensity, says Mr. Tucker, who reported upon it, was magnificently brilliant. At Bovisand the light was sufficiently strong to cast a shadow of objects on a yellow wall, and it was thought to be about equal in intensity to that of the full moon when at its meridian in a calm clear night. At that distance, without the reflector, it looked like the planet Venus when seen through a telescope.

The following are the accounts given of these effects, as seen at Bovisand and Trematon, by Messrs. Walker and Tucker, the two gentlemen who were deputed by Mr. Hearder to make the necessary observations. The accounts are extracted from the *Plymouth Herald* for April 21st and May 5th, 1849. Mr. Walker writes thus:—

"With regard to our observations at Bovisand. About half-past eight o'clock we saw flashes and glimmerings of a bluish light from the column at Devonport, which, to all but myself, were unsatisfactory. The people thought that something had gone wrong. The light was then, in all probability, on the Trematon side of the column, the column being directly between us and the light itself. After waiting for some time, we finally saw the electric light outshining all the other visible lights, and we sent up a rocket or two to indicate our satisfaction. Our personal shadows were projected upon a boat-house door (painted yellow, and itself illuminated) by the electric light, and pronounced equal to that of the full moon when on the meridian in a calm clear night.

"A candle (six to a pound) projected a similar shadow upon the same door, illuminated in the same way, at a distance of 30 feet from the person whose shadow was thrown upon the door. That is to say, the shadow projected by the electric light at a distance of 5,490 yards, was just equal to the shadow projected by a single candle at a distance of 10 yards. Consequently, their illuminating powers were as 10 (squared) : 5490 (squared), or as 1 : 301,401. This comparison is rather a 'stunning' one! I am of opinion that the electric light possesses a space-penetrating power infinitely superior to any light we can obtain by combustion, since it is free from all carbonaceous or solid particles!

"The Breakwater light may probably be equal to twenty-four Argand lamps, each equal to half-a-dozen candles; yet *this* light projected a shadow *only* slightly visible at a distance of 500 yards; while the electric light projected shadows, at lucid intervals, strong enough for children to make *rabbits* with their fingers upon a wall more than 500 yards distant from the light itself; that is to say, ten times farther than from a lighthouse that could only throw a shadow 'faintly visible.' The electric light, as seen in the open air, may be compared (as far as colour is concerned) to that of the planet Venus when seen through a telescope, or to the light of a glow-worm, or to those brilliant flashes of light we sometimes see within the tropics, from the waves when surcharged with phosphorescent matter."

And Mr. Tucker's account is as follows:—"Sir,—A variety of occupations have prevented my sooner informing you of the effect produced here by the electric light, on the evening of the 12th inst. You are aware that this castle is 18,266 feet distant to the N.N.W. from the column at Devonport. The reflector which you used was one from which the rays diverge. The evening was very favourable; but little breeze (E.N.E.) was stirring, yet sufficient to blow off the smoke from the town. The atmosphere was so clear that the Devonport lamps were very distinctly visible, and the stars which appeared shone very brightly; but they were few, and the moon had not yet arisen. The instant the light shone, the lamps of Devonport were all but totally eclipsed: as it fell upon a sail spread over the walls of the keep, we immediately perceived that a shadow was cast by the fingers of a hand upon the sail, by a twig of ivy, and by the stem of an ivy-leaf. We could clearly see what o'clock it was by our watches. I ascertained the light to be polarised, and the whole effect was very striking, for the light upon the column was exquisitely beautiful—its brightness was magnificently brilliant. The interposition of the red shade then informed us that the light would be changed. When that change, whatever it were, was made, the light sensibly increased; we then could see the time by the seconds-hand of a small watch; the usual hand-writing was read; and the ivy-leaves on the gateway tower were seen at the distance of ninety feet. Persons more than half a mile behind the keep could plainly see the walks around it; and we all were very much pleased by the striking effect produced by your turning the reflector upwards towards the clouds, which we clearly saw, the light then having the appearance of the tail of a huge comet, the reflector being the nucleus. I think I may state that the breadth of the intensity of the light was at least three-quarters of a mile; and I believe that persons standing on the brick-field (close to Devonport) saw the light reflected to them from a looking-glass which was suspended from the keep."

If the electric light is exhibited in a room where there are gas or other lights, the intensity of the former is so great that it actually produces shadows of the flames of the others. At the Polytechnic Institution, the electric light is used for the purpose of illustrating the optical effects of refraction and reflection in a stream of water—as seen in Duboscq's fountain. The chromatic effects are produced by means of coloured glass, which is rapidly shifted before the light.

As to the economy of the light, little can be said. Professor Grove stated, that in his experiments with the battery which gave the light of 1,444 wax candles, the cost was at the rate of about 3*s.* or 3*s.* 6*d.* per hour; and Mr. Ward, who has devoted attention to this part of the subject, states, that to obtain a given light with 100 pairs of Smee, 55 of Daniell, or 34 of Grove, each cell consuming 60 grains of zinc per hour, the cost would be about 6*d.*, 7½*d.*, or 8*d.* per hour respectively. But we apprehend that this does not include the original cost of the battery, or the charge for attendance. At the Royal Opera House, where the light was exhibited for several nights in a new ballet, it cost the manager £2 per night, although the exhibition was not of long duration. In this case a Maynooth battery of seventy-five cells was employed.

This clearly indicates that the light can never be economically employed as an ordinary illuminating agent: indeed, it is manifest, that as the source of power is really the same as that of other artificial lights—namely, the oxydation of a combustible body—it resolves itself into this: whether it is cheaper to burn gas, oil, or tallow, by means of atmospheric oxygen, or to consume zinc by the aid of water and very expensive acids. Of course some allowance must be made for the value of the products in the latter case; but then, as a set-off to this, we have to consider the expense of constructing the batteries, and of attending to them. It will, however, be freely admitted, that although it is not an economical light for ordinary purposes, it may be advantageously employed whenever a vast amount of illuminating power is required, and there are facilities for charging the batteries. It might be employed, for example, in light-houses, perhaps also in mines, in theatres, and for public exhibitions of various kinds. It has been stated that the electric light has been used to illuminate the works of the Napoleon Docks in Paris, where the men are employed night and day in their work. The light has been employed there for four months, at a cost of thirty-six francs per night: and as it served for the use of 800 men, the cost was exactly four-and-a-half centimes, or less than a halfpenny, per man. This does not look like a very expensive mode of illumination; and it is very probable that it may be resorted to in such cases as this with considerable advantage. Again, it is not altogether impracticable to have an electric light in some convenient part of a mine, and, by the aid of reflectors, to throw the light along the different galleries, and into the workings. By this means all danger from explosion in those localities where the fire-damp abounds, would be completely obviated.

The Steel Mill of the Miner is the last form of apparatus for the production of artificial light to which we shall allude. Before the introduction of the Davy lamp into the coal-mines of this country, a rude instrument was employed by the miner for the generation of light in those localities where the fire-damp rendered the atmosphere unusually dangerous. It consisted of a small steel wheel, which was made to revolve very fast by means of a small pinion that was turned by hand; and while the wheel was revolving, a piece of flint was held against it, so as to emit a brilliant shower of sparks. These gave out sufficient light for the miner to work by. It was thought that the heat from this apparatus was less dangerous than that from a candle; but Dr. Pereira succeeded in firing explosive gas with it, and thus demonstrated to the Parliamentary Committee that it was just as dangerous in a mine as a candle. At the present time the instrument is quite out of use.

Although the subject of artificial illumination has been fully dealt with in the preceding pages, the following remarks may prove interesting and useful to some of our readers. We have taken each subject separately, and supplementary to what has been already advanced.

Young's Paraffine Lamps.—Mr. James Young, of Bathgate, near Edinburgh, has, for some considerable time past, been engaged in producing an oil for illuminating and other purposes, from a shale known as the Torbanehill mineral. With respect to this substance, we may observe, that there is hardly anything in the way of scientific discovery which has proved so difficult to classify. Nearly every eminent chemist in Europe has been called on to decide as to its nature; the question being, whether it should be regarded as coal, or as a mineral substance. Owing to the terms of the lease, the lessors reserved their rights to the minerals on the property; whilst the lessees object and resist all claim on them, by asserting that the substance from which the oil is obtained does not fall within that category. Advertisements have been freely distributed in the leading papers by the lessors, since the commencement of this year (1861), inviting all competent persons to afford their advice and assistance; and as the means of warfare are not wanting on either side, and as the prize is of almost fabulous value, we may expect to find a most exciting contest before the Court of Session, in Scotland, at the impending trial of the case. The object is to invalidate Mr. Young's title in the question, so far as his patents are concerned—the right to use the material having been compromised by the parties.

Paraffine itself is so well known as to require no description; and Mr. Young uses a form of lamp similar to the one already illustrated.* Such are, however, modified as to size, ornament, &c.; and the paraffine lamp may now be seen in the humblest cottage, and in the residences of our nobility, so popular and general is its use.

The Fitzmaurice Light.—This invention caused a considerable sensation amongst naval circles, on account of its brilliancy and portability. For some time its arrangements were kept secret; but it is now stated that it is simply a modification of the lime light, the gases being kept in small reservoirs, into which they are pumped to a high pressure.

The Lime Light.—This light has lately been partially used for street purposes; and for the sake of introducing it into popular notice, one side of Westminster-bridge was lighted up with it. A company was formed to carry out its general adoption. We believe, however, that nothing further has been done than what we have mentioned; and until a cheap and ready mode of obtaining oxygen is discovered, it is very unlikely that the lime light will be generally adopted.

The Electric Light.—This subject we shall fully enter into hereafter; but we may just mention, that Mr. Holmes has, within the last few years, made a considerable improvement in obtaining electricity, by constructing a large magnetic machine, which is driven by steam-power. Coils of wire, enclosing bars of soft iron, are opposed to powerful magnets. These rotate rapidly, and, each time of passing the coils, a current of electricity is produced. In 1856, we were present at a trial of its powers, at the premises of the Trinity Board, Blackwall; and we can, perhaps, give no better illustration of the effect of this light, than by stating, that we could easily detect the divisions or panes of a window in a house a mile distant, when the light was concentrated by means of the ordinary lighthouse lenses. The apparatus was subsequently transferred to the South Foreland; and nightly, for six months, without a moment's interruption, the light was maintained, casting its brilliancy across the Channel, and being distinctly seen on the French coast.

---

* See *ante*, p. 113; Fig. 117.

We shall reserve our further remarks on the electric light for the section of Electricity, under which it will more conveniently be discussed.

CHAPTER IV

PHOTOGRAPHY.

Having, in our former pages, entered fully into the examination of the phenomena and laws of light, we are prepared to deal with one of the most interesting applications of physical and chemical science—namely, the art of taking pictures by the agency of light. We shall have to introduce the subject by referring to some of the laws and facts of chemistry; because, although photography is an application of the effects of light as an agent, the process is an entirely chemical one so far as the operator is concerned.

The power of light in changing the ordinary colour of objects, is far more universal than is generally supposed. Most of our readers must have noticed that some delicate colours speedily fade when exposed to the full light of the sun. This effect is undoubtedly due to some action produced by the rays of light on the substances with which a material has been dyed. Light-blue and pink silks are thus easily faded. Sir John Herschel, in some masterly researches, published a few years ago in the Philosophical Transactions of the Royal Society, pointed out, that all the juices of any flower are thus acted on by light. Indeed, we may state generally, that the cause of the varied colours of our landscapes and flowers, is simply that of a process analogous to those employed in photography. One of the simplest illustrations of the kind we can offer, is that of the different appearances of the inside and outside of some vegetables, such as celery, lettuce, and the cabbage. The external leaves which have been freely exposed to the direct solar rays, have a deep green, or, in celery, a red colour; whilst the inner leaves, which have been protected from light, always present a pale or blanched appearance. Even the human face may be taken as another instance of the same kind; for we observe the ruddy glow and deep colour in the rustic, presenting a bright contrast to the sallow, pale, and unhealthy appearance of the factory operative, or the resident of our large cities. Light, indeed, has a colourising and a sanitary effect, to an extent little dreamt of by those unacquainted with the science of physiology.

Photographers, however, avail themselves almost entirely of the metal silver as the great medium of their operations. When that well-known metal is united with certain substances, the resulting compounds are rapidly affected by light; and on exposure thereto, become changed to a dark colour. The whole art of photography may be almost summed up as existing in the choice of the salts of silver, their proper application, and immediate removal when the desired effect is gained. It is true that many other substances may be similarly employed; but, in practice, they are of comparatively little independent worth.

It will be impossible to go into the entire history of this most interesting art, for its inventors and improvers are indeed "legion." Suffice it to say, that we are indebted to Mr. Wedgwood and Sir Humphry Davy for the initiative of our processes; and, since their day, MM. Niepce and Daguerre, in France, and Messrs. Talbot, Archer, Hunt, Sir John Herschel, and a host of other eminent men, have, by their intelligence and practical skill, raised to the highest rank as a philosophical study, and as a social and artistic occupation, that which, twenty years ago, was but barely named in ordinary scientific works.

It will be our endeavour to discuss and illustrate the principles and practice of photography in as plain a manner as possible. For the sake of saving space, we shall assume that our readers, through our previous pages, have become acquainted with the various optical laws, instruments, &c., to which we have alluded. This will prevent tedious and unnecessary repetition. The chemical processes we shall describe as if we addressed those who are unacquainted with chemical science; and whilst giving a variety of details as to processes employed or recommended by different individuals, we shall mostly keep in view those which are simple, effective, and easy of prosecution by persons of ordinary intelligence, and limited scientific attainments.

INTRODUCTORY EXPERIMENTS.

We commence by introducing the experimenter to a few illustrations, which will give a general idea of the nature of photographic processes, and which he will do well to repeat until a certain amount of ease in manipulation is gained. We must, however, preface our remarks by urging on all a great point, without attention to which all attempts at photographing must surely fail: we refer to *scrupulous cleanliness*. Neglect of this, and carelessness, are the two chief causes of all the disappointments both of the tyro and practised operator; and to impress the necessity of our advice being attended to, we shall suggest an experiment, by which the cleanest hands may be proved to be photographically dirty on many occasions.

Experiment 1.—After washing and drying the hands in the usual manner, allow them to remain some time in distilled water, afterwards frequently rinsing them therein. Add to the water a solution of nitrate of silver: in a short time the water will assume a milky appearance, owing to the common salt exuded with the perspiration from the skin, forming a substance with the silver, called chloride of silver. If a little of the solution of nitrate of silver be added to pure water, no salt of the kind we have named will be produced.

It will thus be seen how, in every case, the photographer carries with him the instruments of his own destruction. Whenever a piece of paper or glass is touched by the fingers, then a spot of common salt, grease, and organic matter is left: these acting on the silver salts, produce patches and spots which spoil any photograph. We trust that our readers will be by this, fully persuaded of the necessity of care in this respect, and thus they may prevent the numerous annoyances to which their neglect would otherwise expose them.

The salt formed during Experiment 1, is called the chloride of silver, because the chlorine in the common salt from the hand, has joined with the silver contained in the nitrate of that metal. We must here state, that the term "salt" is applied by the chemist to a vast range of substances; and generally, whenever an acid is united with an earth or an alkali, a "salt" is formed. Thus nitre, or saltpetre, is composed of nitric acid and potass, and is called a salt of potass. Its name is partly derived from the acid, the nitric, and partly from the base, the potass. Hence the chemist terms it the nitrate of potass; and by this system of naming salts, he instantly sees, by the name, what the salt is composed of. Our common table-salt is called, in chemical language, chloride of sodium, because it is composed of a gas called chlorine, which produces the smell of bleaching powder, with a metal called sodium, found in soda, &c. The reader having mastered this system, will at once see its great value; and although perhaps experiencing at first some difficulty in acquiring names of salts, he will speedily reap the advantage of the general nomenclature.

To save repetition of terms, we shall, in future, call a solution of the salts of silver, *the silver solution;* and solution of common salt, *the salt solution;* and for our introductory experiments, these may be made as follows:—

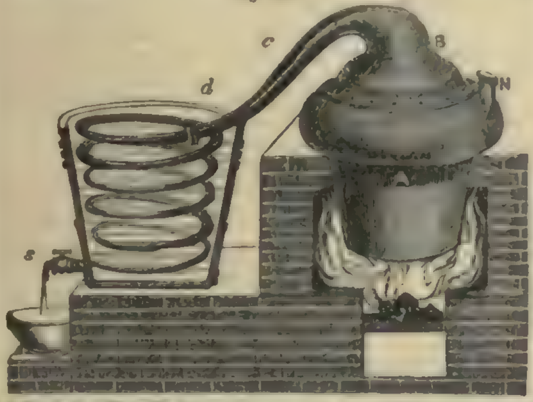
To make the "Silver Solution."—Dissolve fifty grains of crystallised nitrate of silver in one ounce of distilled water.

To make the "Salt Solution."—Dissolve sixty grains of common salt in four ounces of clean water.

It will be observed that we have mentioned, that *distilled* water must be employed to dissolve the nitrate of silver. This is because river and spring water contain common salt. Distilled water may be procured of the chemist and druggist, or may be made by affixing a long pewter tube to the spout of an ordinary tea-kettle. As the steam passes from the kettle it will be condensed in the tube, if the latter be kept cold by means of wet rags, or by being immersed in cold water. The distilled water may be received in clean glass vessels, which should be kept stoppered and free from dust.

A useful still may easily be constructed by an intelligent smith; and such as is represented in Fig. 141 is a convenient form.

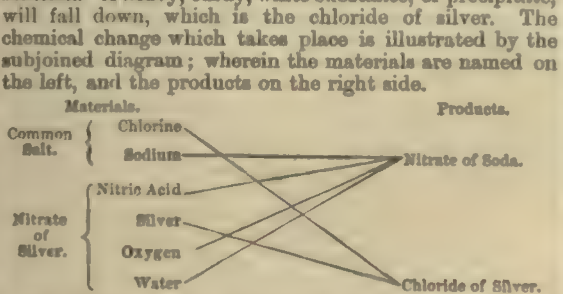
Fig. 141



A is the body of the still, into which the water to be distilled is introduced. Round this vessel the fire is placed. B is the head of the still, through which the vapour passes by means of *c*, until it arrives at *d*. *d* is the worm, surrounded by cold water. In this part the steam is condensed, and escapes, as distilled water, at the tap *s*, where it may be collected in bottles, which should be kept carefully corked.

The solution of the salts of silver should always be kept in a glass-stoppered bottle, and surrounded with a piece of black paper, or kept in a dark place, so as to prevent the action of light.

Experiment 2.—Pour some of the salt solution into a wine-glass, and then add a few drops of the silver solution. A heavy, curdy, white substance, or precipitate, will fall down, which is the chloride of silver. The chemical change which takes place is illustrated by the subjoined diagram; wherein the materials are named on the left, and the products on the right side.



The result of the mixture is, that the chlorine and silver unite together to form the chloride of that metal; and the nitric acid, sodium, and water form the salt, nitrate of soda, which is dissolved in the liquid. We have thus an instance of chemical decomposition, and the formation of new compounds.

Experiment 3.—Divide the white powder obtained in the last experiment into two portions, and keep one part in a dark place, and expose the other to the rays of the sun. In a short time, the portion left in the light will turn to a dark mulberry tint, owing to the action of the chemical rays on the salt; whilst that kept in a dark place will remain entirely unchanged.

By these experiments the student will learn the elementary principles of the art of photography; and may now proceed to the next step, that of preparing paper which will be sensitive to the action of light.

Experiment 4.—*To prepare Sensitive Paper.*—Pour the salt solution into a clean plate, and place on its surface a piece of white writing-paper, leaving it there for some time, so that the solution may enter the pores of the paper. The salted side should then be marked with a black-lead pencil, so as to distinguish it from that which is unsalted. The paper may then be hung up to dry. The next process is to render the paper sensitive to the action of light; and is effected by placing the salted side, face downwards, on the silver solution contained in a clean plate, and leaving it there for about ten minutes. The paper is then to be dried in a place to which light has no access. This part of the preparation of the paper should be done by candlelight; and several sheets may thus be made and kept, till required, in a portfolio or book.

Paper thus prepared will at once change its colour on being exposed to diffuse daylight, or in the sun's rays; and if any opaque object be placed over it, a complete copy of its form may be procured. If a penny-piece, for instance, be placed on a sheet of this paper, and exposed to sunlight, all the uncovered portion will be turned to nearly a black colour; whilst that under the coin will retain a white and unchanged appearance, because there no light has reached, and therefore no chemical effect could take place. On removing the coin, the white part will become changed, if exposed to the light; and this introduces us to another process—namely, that of "fixing" the picture obtained as above.

The fixing process is intended to dissolve away that portion of the silver salt which has not been acted on by the light; and it will thus prevent a picture, when obtained, from being spoilt or lost. The solution used for this purpose is that of a salt called hyposulphite of sodium, an ounce of which may be dissolved in four ounces of water. The picture is to be left on this solution, face downwards, for a short time, and afterwards well washed in abundance of cold water. After being dried, it may be exposed, without any danger of undergoing further change; in fact, it becomes permanent and unalterable.—If, instead of a coin, a piece of lace, a fern-leaf, or other such object be placed on the paper, and pressed thereon by means of a piece of plate-glass, a complete copy of it may be taken: a child's transparent slate is a very convenient arrangement for this purpose; but the ground-glass plate must be replaced by a piece of window or plate-glass, so that the light may freely pass through. By this simple plan a vast number of objects may be copied; the solid parts being represented by white spaces, and the transparent portions by dark marks on the paper. This process is so exceedingly easy, that any young person may readily follow the directions we have given. We may here remark on the advantages which elementary science affords in training and disciplining the young mind. The ordinary course of juvenile instruction, has the twofold object of teaching facts, and preparing the mental powers for future and more exact duties. If, however, we can find any means by which amusement, interest, and instruction can be combined, such become a most valuable adjunct to an educational course.

We have now to notice that there are two classes of photographs; namely, *negative* and *positive*. By the former, the dark portions of the object are represented by light parts in the picture; but in a positive, the appearances are the same as in the object which has been copied. Fig. 142 represents a negative, and Fig. 143 a positive, of the same object.

Fig. 142.

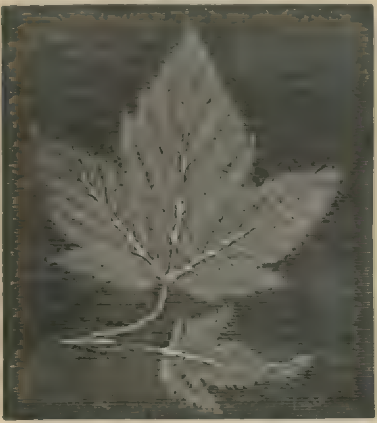


Fig. 143.

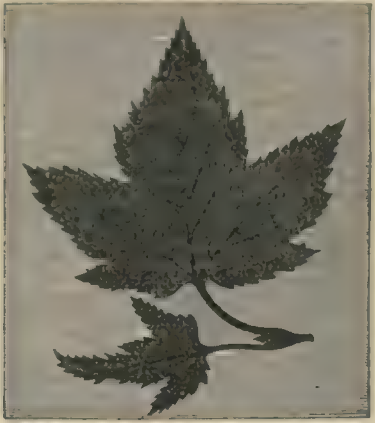

A positive picture may easily be obtained by placing a negative, face downwards, on another piece of prepared paper, and proceeding as before. The light will thus pass through the unchanged portions of the negative, and so produce a darkening of the paper beneath it; whilst the dark portions of the negative, of course, prevent any change in that part of the paper beneath them. The positive, thus obtained, may be fixed by the process previously described.

We have purposely restricted these experiments to the simplest form of photographic practice. The materials are easily obtained; and if the process be repeatedly performed, the student will gradually acquire an expertness, and, at the same time, meet with difficulties which he may easily overcome. If, for instance, he observe brown marks on the picture, he may guess that his fingers have been their cause. White, round spots indicate places where neither the salt or silver solution have touched the surface of the paper, owing to the presence of air-bubbles. Blotches, and large patches on the surface, show that the paper is not suitable for the purpose. This may easily be avoided by the purchase of an article specially prepared for photography; but we still recommend that the tyro should begin in the simplest manner, and so arrive, step by step, at success, by becoming gradually acquainted with obstacles as they accidentally present themselves.

To save trouble, and to simplify our instructions in these elementary attempts, it may perhaps be as well that we give a recapitulation of the whole of the process; and also special directions for obtaining positive copies from negative pictures.

1. Salt one side of the paper, taking care that no air-bubbles are left between its surface and the liquid.

2. Mark the salted side.

3. Dry the paper.

4. Render the salted side of the paper sensitive by placing that surface in the silver solution for about ten minutes, taking precautions against the presence of air-bubbles, by drawing the paper over the solution whilst holding it at one corner. This must be done by candle-light.

5. Dry the paper in a dark place, and, when dry, keep it out of the light.

6. To obtain a negative picture, place the object on the sensitive surface of the paper, and press thereon a piece of plate-glass, so that the object and paper may be in the closest possible contact.

7. Expose to day or sun light so long that the paper may acquire a dark mulberry tint in those places where the light has free access.

8. When the picture is finished, remove it into a dark room, and fix by means of a solution of hyposulphite of sodium.

9. Wash abundantly in cold water, so as to remove all trace of the salts. This should be done by placing the picture in a basin of water for some hours, and meanwhile frequently moving it in the liquid.

10. The picture may then be dried, and pasted or gummed on a piece of cardboard.

11. To obtain a positive picture from a negative, place the negative, face downwards, on a piece of sensitive paper, the two being pressed together by means of plate-glass, or otherwise. When the picture is finished, proceed as recommended in Nos. 8, 9, and 10.

If resident in any of our large towns, the operator may purchase paper which is ready salted, and also covered with albumen. This only requires to be excited by placing the albumenised side on the silver solution, as named in No. 4. This paper may be prepared by dissolving fifty grains of salt or sal-ammoniac in two ounces of water, to which twice as much of the clear white or albumen of an egg has been added. The mixture must be well shaken together, and then strained through muslin. The paper may then be laid on its surface after the manner before recommended for the salting process. The albumen gives a nice gloss to the picture, and so greatly improves its appearance.

We need scarcely state, that an ingenious person may employ the above process to a vast variety of interesting and amusing purposes. Leaves of trees, flowers, ferns, engravings, lace patterns, and an immense number of similar subjects, may thus be easily copied: indeed, we know of no branch of scientific application so readily acquired, and more varied or interesting in its pursuit.

We may here mention, that the ordinary process of marking linen by means of common "marking-ink," and various modes of dyeing hair, are really but applications of photographic principles and practice. In most of these cases, solutions of the nitrate of silver are employed; and the results obtained are identical with those we have named, except so far as the objects to which they are applied are concerned.

Having thus attempted to introduce the reader to some of the most elementary instances of the practice of photography, we now proceed to describe more intricate processes, by means of which the highest class of effects are obtained; and which will of course require greater attention, care, and perseverance in their pursuit, than those to which we have hitherto referred.

PHOTOGRAPHIC APPARATUS AND CHEMICALS, Etc.

Before proceeding to detail the various processes now in use, we shall enter into a description of the apparatus which will be required by the student, and also mention the different chemicals employed by photographers.

The chief photographic instrument is the camera. We described some forms of this instrument under the head of Optical Instruments; but such are of far too incomplete a kind to be employed for photographic purposes, in which the utmost accuracy of construction hitherto attained has yet left many defects to be overcome. We shall therefore endeavour to point out, not only the best form of the instrument for various purposes, but also shall suggest contrivances which may assist the beginner in many circumstances in which he may be placed.

A camera of an ordinary kind, suitable for a beginner, may be procured for a moderate sum; but where the means of the student will permit, none but the best kind, as to construction and character of the lenses, should be employed. Many persons commencing the practice of photography, are content to do so with an inferior instrument. Having thus to contend with difficulties which, from their want of knowledge of the science of optics, they can neither overcome nor control, they often entirely fail in obtaining good results, and, consequently are soon discouraged by failure. Our remarks on aberration[*] will at once suggest to the intelligent reader, that the construction of an accurate camera depends on an extended acquaintance with the laws of optics, combined with a high degree of skill on the part of the maker; and of course such acquirements both demand and deserve an adequate pecuniary recompense; hence the high price of some cameras employed in the art. If a lens could be ground of such an exact shape as to overcome the occurrence of spherical aberration, as easily as the difficulty of chromatic aberration has been dealt with, such would, of course, almost arrive at perfection. We here observe how exact are the works of the Deity compared to the best productions of human skill. In the eye we have every change of circumstance at once provided for, as we have already explained when treating on the eye and its structure. Now, the lens of the camera has to fulfil the same object as the crystalline lens of the eye; and to extend our analogy, we may add, that the prepared plate of the photographer is the analogue of the retina of the eye; for, like it, it has to receive and communicate impressions of the rays of light incident on its surface.

It would, of course, be highly improper for us to recommend any instrument-maker, in preference to others, of whom the student might purchase his camera, and other photographic apparatus. We, however, shall attempt to explain the advantages and improvements which have been introduced by various persons; and giving the student an opportunity of judging of the essential points to which his attention should be directed, we must leave to his own judgment and preference, the particular form, &c., of the instruments he may desire to obtain. Two classes of cameras, or at least two sets of lenses for the camera, are necessary, for the separate purposes of taking likenesses and landscape views. This will be evident when it is remembered that, in the first instance, the object may be placed close to the instrument; whereas, when taking a photograph of a country scene, &c., the different objects will be at all possible distances from the centre of the lens. The human eye is capable of adapting itself instantaneously to the variations of distance in respect to objects seen by it; and to a certain, but not entire extent, the same result is effected in the position of the lenses of a camera by a mechanical arrangement—the operation being termed "*focussing.*"

In the annexed engraving, the general arrangement of the photographic camera is represented. In Fig. 144, A represents the box of the camera; B a brass tube in which the lenses are placed; C a slide or dark frame, in which the sensitive plate is fixed. In Fig. 145, D shows this frame in its details; the back being opened, so that its internal construction may be observed.

Fig. 144.

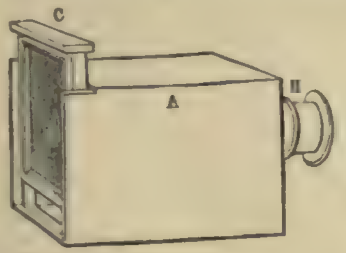

Fig. 145.

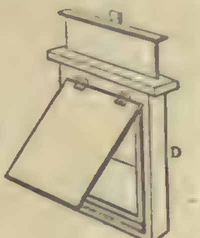
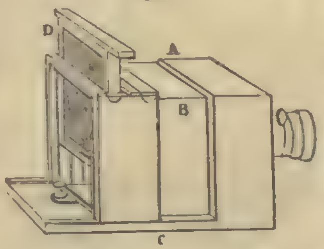


The image received on the ground-glass plate at C, in Fig. 144, is focussed in this form of camera, by moving or adjusting the lens contained in the tube B in front of the camera; hence its use will be necessarily confined to occasions wherein such limited adjustment is admissible or required. Another form of the camera, in which the distance between the ground-glass plate for viewing the image, and the tube in which the lenses are placed, is illustrated in the following engraving.

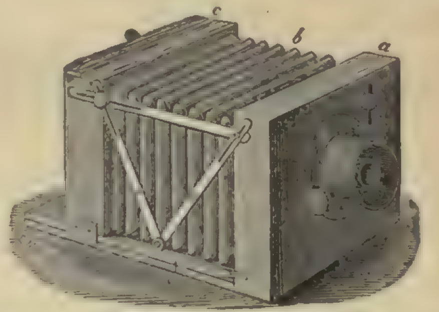
In Fig. 146, we observe that the box of the camera is divided into two parts, of which B is so constructed as to slide easily in and out of A. Thus the ground-glass plate represented in the frame D, may be extended to and fro from the lens, and a greater focal arrangement can be arrived at.

Fig. 146.



A very convenient form of camera, for travelling purposes, is represented in Fig. 147. The body of the box, instead of being solid, is made exactly like the bellows of the concertina. The back, *c*, holding the plate, can thus, by means of the folding construction of *b*, be easily shifted any distance from *a*, the part of the arrangement holding the lenses; and all parts are maintained in a firm condition, when in use, by means of the crossbars *d d*. These are secured in any desired position by means of screws working through slots in the bars.

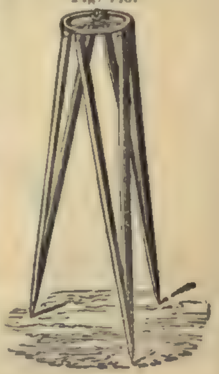
Fig. 147.



We need not, however, occupy further space by details of those forms of the camera which result from the peculiar choice, requirements, or means of the operator. Any, or most of these, may be inspected at the optical instrument-makers, who, according to their individual opinions on the subject, will be able to give more precise and effective descriptions than it falls to our province to attempt. We may, however, offer a word of advice to those who may be desirous of purchasing an instrument; and, in so doing, we need scarcely state, that the purchaser will do wisely to seek his apparatus at any house whose reputation for skill and respectability is well attested. Achromatic and properly ground lenses, their transparency, firmness of workmanship in the material of the box, are the essential points. We have seen cameras made of unseasoned material, in which some of the parts of the woodwork have contracted by change of weather, which rendered them extremely inconvenient, not to say useless. In such cases, the dark frame, by fitting too tightly or loosely in the slide receiving it, will often cause the camera to be shifted whilst introducing the sensitive plate, and so entirely remove the camera itself out of position, and destroy the focus. We can only add, "*caveat emptor.*"

The camera requires a steady support, and one which can be adapted so that it may be placed in any position. One of the most convenient of these is that represented in Fig. 148; and one of this kind is equally available for house and out-of-door use. Great care should be observed in purchasing or making a stand of any shape, because the use of unseasoned wood soon

Fig. 148.



---

[*] See *ante*, p. 53.

causes them to become unsteady, and makes them utterly valueless.

Amongst the minor, but essential apparatus of the photographer, are the following.

Fig. 149 represents the dipping-bath, and frame for holding the plate in the silver solution contained in the bath.

Fig. 149.

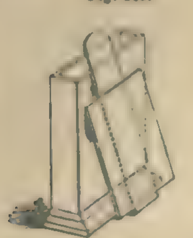


Fig. 150

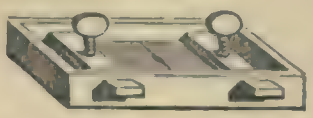

Fig. 150 is a representation of a copying frame, by means of which positive copies are obtained from negative pictures. It is an improvement on the simple arrangement of the child's transparent slate, to which, and its use, we have previously alluded.*

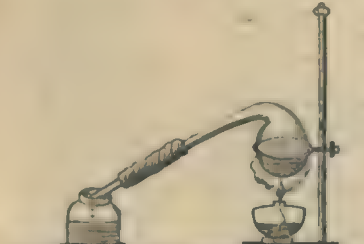
We have thus referred to some of the most essential arrangements required by the reader when commencing the study of photography. We shall allude to, and illustrate, various contrivances which have been invented for the purpose of facilitating several operations, as we proceed.

In our humble opinion, it is better that every student of science, whatever his means may be, should commence with as few "assistants" as is consistent with his progress. He is thus thrown on his own resources; he sees his wants; his ingenuity is stimulated to supply them; and his progress is infinitely more satisfactory to himself, and advantageous to others in every department of scientific research, than when he is helped over every little obstacle that may drop across his path. Both morally and mentally, "he that chiefly owes himself unto himself, is the substantial man."

Besides the different apparatus we have described, the tyro will require some glass-stoppered bottles of about four ounces capacity; square dishes of glass or porcelain for holding developing solutions, &c.; two or three graduated glass measures, of two ounce, one ounce, and one drachm capacity; some glass rods for stirrers; and a dozen or so of test-glasses, which, however, may be replaced by ordinary uncut wine or ale-glasses. He should also possess a spirit-lamp, of four or eight ounce size, and a small ring-stand, for supporting glass vessels in preparing solutions by heat; some glass funnels for filtering solutions, &c.; some filtering papers, or, what is nearly as good, some stout white blotting-paper; and last, and by no means the least of his requirements, is that of an unlimited supply of clean, soft towels, and of rain or soft river water. The quality of ordinary water differs very much, according to the source whence it is obtained: when hard, distilled water should always be used.

We have mentioned that distilled water is essential in many of the operations of photography; and we refer our readers to the remarks made in reference to this subject.† When required in but small quantities, it can be made by using a pint-glass retort, supported on a ring-stand. A spirit-lamp may be employed as a source of heat; and the stem of the retort should be kept cool by means of wet cloths. (See Fig. 151).

Fig. 151.



PHOTOGRAPHIC CHEMISTRY.

In the ordinary arrangement of a scientific work, it is almost a question of choice as to whether photography might be considered an application of chemical or of optical science. As we have adopted the latter idea, we shall necessarily have to introduce our readers to so much of the science of chemistry as will enable them to understand the rationale of the processes in which they must engage. This will by no means prove any hindrance; indeed, had the student to forage out, on his own account, such a knowledge of chemistry as he will require, we imagine that he would thus effect a much larger expenditure of time and means, and would, most likely, obtain a much less satisfactory result, than if he simply studied and followed the *excerpta* and directions of those who are more fitted by experience to point out and prepare the way for him.

With this end in view, we shall now direct briefly the reader's attention to some of the leading applications of chemistry, so far as they are required in the photographic art; referring him, however, to the remarks which we have already made on this subject in our introductory experiments.‡

To one or more of three substances (chlorine, iodine, and bromine) the photographer is indebted for his most successful results; and the student may become acquainted with their specific characters by trying the following experiments:—

Experiment 5.—Chlorine may be obtained in various ways. It is a constituent of common salt, &c. Place a teaspoonful of chloride of lime (bleaching-powder) in a glass bottle or jar; pour on the powder a little hydrochloric (muriatic) acid and water; in a little time, gas will be given off, and will gradually fill the jar. It has a greenish-yellow colour; hence the name, chlorine, from the Greek. Its smell is very penetrating; and if a piece of paper, coloured by litmus or any other vegetable, be dipped therein, it will be immediately bleached. Hence the employment of chloride of lime in the manufacturing districts, for bleaching cotton and linen goods.

Experiment 6.—Iodine. This substance is obtained from sea-water, and was first discovered by its action on the pans in which salt was evaporated. In its ordinary state, it is a dark-coloured powder. Heat a little of this on a plate, and observe the colour of the vapour, which will be of a rich purple; and thence has arisen the name of the substance. Combined with potassium or potass, it forms the iodide of potassium, or hydriodate of potass; names which are used for the same salt. Iodide of potassium is largely employed for a variety of purposes in photography.

Experiment 7.—Bromine. This is always sold in a liquid state; and, like iodine, is obtained from sea-water. It has a deep orange colour, and most offensive smell. Expose a little of the liquid bromine to heat; its characteristic vapour will be at once noticed: the fumes, however, which are extremely irritating, should be avoided. Bromide of potassium—that is, bromine and potassium united together—is the combination most used. Bromine and iodine are used, together with collodion, in the liquid state for the collodion process; whilst, as vapour, they are employed for making the silver plates of the Daguerreotype process sensitive, before being placed in the camera.

These three substances, chlorine, iodine, and bromine, have been termed elementary bodies, because they have resisted all attempts at decomposition; that is, by the exercise of all our knowledge of chemical science, we have been unable to find any other substance in them different to their own nature or characters. This fact leads us to remark, that the union of such elementary bodies with others, forms a class called compounds. Of such are common salt, composed of chlorine and sodium, and the iodide and bromide of potassium, which we have just referred to in our experiments.

The most essential element of photographic art, is the metal silver. This is never used in the state we observe it in our silver coins, because it is therein alloyed with copper, to give it sufficient hardness to withstand the wear and tear of daily use.

---

* See *ante*, p. 141.

† *Ante*, p. 141.

‡ See *ante*, p. 140, *et seq.*

Silver is employed both in the metallic state and in the form of nitrate of silver: the former is used in plates for the Daguerreotype process, or as plating or covering a sheet of copper; and the salt is universally used in the calotype, the collodion, albumen, and other processes of photography generally.

The salt, nitrate of silver, is easily formed, by putting a piece of pure silver in a little nitric acid diluted with water. A violent action takes place; the metal is dissolved; and by evaporating the solution, crystals of the salt are easily obtained. It, however, is far better that the operator should purchase the salt at a photographic chemist's or instrument-maker; as such prepare it more especially for photographic purposes, and thus avoid a variety of impurities which are ordinarily found in the nitrate of silver of commerce. It may perhaps be as well for us to remark, that all photographic chemicals may be procured by post from any of the leading towns in Great Britain and Ireland. This may be valuable information to those resident at a distance from such places. In our own journeys, we have met with several "towns" so called, wherein we could not purchase a chemical of any kind; and while writing this, we have in our mind's eye two places in Scotland, containing each over two thousand inhabitants, wherein neither medical man or chemist and druggist could be met with, or could their professed wares be obtained at any price—a fact which unutterably astonished us, considering the prevalence of "medicinal taste" amongst us as a people.

On adding a salt containing chlorine, iodine, and bromine, to nitrate of silver, other substances are formed, being respectively the chloride, iodide, and bromide of that metal. The chloride of silver is a white powder, turning to a dark mulberry tint on being exposed to the action of light. The iodide of silver is of a yellow colour, as is also the bromide; each being produced on adding either the iodide or bromide of potassium to nitrate of silver. These salts are formed when a plate, covered with iodised and bromised collodion, is dipped into a bath of nitrate of silver—a process into which we shall extensively enter when we consider and describe the usual method of taking likenesses, &c., by means of collodion.

In chlorine, iodine, bromine, and their salts, or salt-like combinations, we have described the chief active agents employed in photography; and in silver we have the substance acted on by them. The resulting products of their mutual action are the media which the photographer employs directly to obtain his result; but these have to be placed or used in combination with others. His chemicals are as the colours of the painter; whilst his collodion, &c., take the place of the painter's canvas.

Collodion, like its basis, gun-cotton, is of very recent discovery; but it has done more to extend and render popular the pursuit of photography, than any other invention which has been connected with the art; and the process deriving its name from the substance, at once affords beautiful and satisfactory results. Whilst we urge on our readers the wisdom of purchasing, rather than of attempting to make their collodion, we shall give a general direction as to its manufacture, so that its composition, &c., may be fully understood; and to this end we suggest an experiment by which gun-cotton may easily be made.

Experiment 8.—Put some perfectly clean jewellers' cotton, or cotton wool, into a glass jar, or a common tumbler. Mix in a porcelain vessel equal parts of strong sulphuric and the strongest nitric acid; and, after stirring these together, allow the mixture to cool. We name a *porcelain* instead of a glass vessel, because of the great heat produced, which would almost certainly destroy glass. The mixture should also be made in the open air, or in a place where a draught would carry off the suffocating fumes which are given off. When the acids have cooled, pour them on to the cotton wool, and press them together repeatedly for about five minutes by means of a glass rod, so that every part may be well moistened with the acids. It then should be removed by means of the glass rod, and washed under a tap of running water, until every vestige of acid is removed. This can be judged of by the taste of the water as it runs away. The cotton may then be pressed between a clean cloth; and afterwards being opened out, so as to expose plenty of surface to the air, it may thus be dried either in the sun or in a warm room. Artificial heat should only be used with great care, because an explosion might ensue if too great heat be applied. Blotting-paper, sawdust, &c., may be treated in a similar manner, and they will undergo identical chemical changes.

If the cotton thus prepared be ignited, it will be found to explode suddenly like gunpowder, and not in the slow fashion that takes place when common cotton wool is placed in a flame. Indeed, the substance has been frequently employed instead of gunpowder for blasting purposes. It, however, undergoes too rapid a combustion to be of use in rifles, cannon, &c.; and is a dangerous agent if so employed, generally causing the bursting of the piece. We have lately been informed, by a friend, that in the summer of the past year (1860), it was successfully adopted by the Austrian service to a considerable extent.

Having thus obtained the gun-cotton, or, as it is chemically termed, "pyroxyline"—the next step is to dissolve it, and so to form collodion. This is done by adding a few grains of the cotton to a mixture of six parts of ether with three parts of alcohol, highly rectified; or the following proportions may be taken:—

Gun-cotton . .	10 grains.
Ether . . .	half an ounce.
Rectified alcohol .	quarter of an ounce.

These should be added together in a glass-stoppered bottle, and, after a short time, the greater portion of the gun-cotton will dissolve, and this solution will be collodion.

If a little of this solution is dropped on to a glass plate, the spirit will soon evaporate, and a fine film will form on its surface. It is this film that is employed to hold the chemical agents which are subsequently placed on its surface, and by whose changes, under the action of light, the photographer effects his beautiful results.

The collodion thus prepared, requires, however, other additions to fit it for use; and these consist of substances which, by their action on the silver solution in which they are afterwards placed, render the coating sensitive. For this purpose, iodide of potassium, iodide of ammonium, or that of cadmium, may be added to the collodion. The iodising of the collodion is a question on which almost every operator differs; and it is, to a large extent, an empirical subject. We shall, therefore, state generally, that the addition of a few grains of either of the three salts, iodide of potassium, ammonium, or cadmium, to the quantity of collodion manufactured as we have just directed, may be employed by the student. We still however, only mention this that he may understand the constitution of iodised collodion; and, as before, advise its purchase as ready prepared. The uses and modifications of this liquid we shall fully consider hereafter.

We have thus dealt with most of the substances employed for the ordinary processes so far as preparing the plate for the camera is concerned. We now proceed to speak of others which are employed for developing and fixing the pictures on the removal of the plate from the camera after its exposure to light, referring chiefly to those of the collodion process. Omitting alcohol and ether, we shall chiefly refer to those which are most in demand; and shall thus avoid distracting the attention of the operator by too extended a description.

The following acids and salts are variously employed for developing solutions; namely: acids—acetic, gallic, pyrogallic, and nitric; salts—protosulphate, and protonitrate of iron. Acetic acid is the basis of the vinegar of household use; but for the purposes of the photographer, a pure and strong kind is required. It is generally sold by the photographic chemists, under the name of glacial acetic acid, which is its strongest state, and which will assume the solid form when at a temperature near the freezing-point of water.

Gallic acid is produced by the decomposition of gall-nuts, which are freely exposed for a few weeks to the action of the air and water. Pyrogallic acid is obtained by the action of heat on gallic acid; and is largely used in the collodion process; whilst gallic acid is equally so for the calotype.

Nitric acid is employed for various purposes as a photographic agent. Its usual source is nitre, whence it is obtained by distilling that salt with sulphuric acid and water.

Protosulphate of iron is well known under the name of green copperas, although not a particle of copper enters into its composition. It is composed of iron and sulphuric acid, and may be obtained by adding these together. In a pure state it is sold in the form of rich green crystals, and is much employed for developing-solution. Protonitrate of iron, which is also similarly used, is composed of iron and nitric acid, and may be made by mixing together a solution of sulphate of iron, and one of nitrate of baryta. For making small quantities of this salt in solution, 100 grains of each salt should be dissolved in water in separate vessels. On the two solutions being mixed, a white powder, the sulphate of barytes, will fall down; and being filtered from this, the solution will contain the protonitrate of iron.

Having thus disposed of those acids and salts mostly employed in the collodion process, we conclude by referring to two substances used for the purpose of fixing the picture, or, in other words, to remove the unchanged salts of silver, and so to prevent any further chemical change being produced on its subsequent exposure to light. Hyposulphite of soda is largely prepared for photographic "fixing," and is accordingly a cheap and easily procured salt. The strength of solution required will be mentioned when we further refer to its use. It is obtained by transmitting sulphurous acid through a solution of carbonate of soda. Sulphurous acid is a product of the combustion of sulphur, and may be abundantly obtained by heating sulphuric acid with the metal mercury in a glass retort.

Cyanide of Potassium.—This salt has lately come into great use as a fixing agent, and is also largely employed in electro-plating and gilding. It is generally procured by heating together, in fine powder, one part of dry carbonate of potass with two parts of ferrocyanide of potassium (yellow prussiate of potass): a white deliquescent powder is the result. We may here warn the student, that this salt is a most deadly poison, owing to the presence in it of cyanogen (the base of prussic acid); and he will act wisely in avoiding the smell which arises from its solution: he should also be cautious in immersing the hands, especially if they are at all wounded, or the skin abraded. This salt should be kept in close-stoppered bottles, as it readily absorbs moisture from the air.

We have thus endeavoured to give a general idea of the nature and uses of those substances employed as chemical agents; and as the collodion process is one which is easily managed by a little care and patience, we shall commence our directions in practical photography therewith, reserving any further remarks, both on apparatus, chemicals, and other matters, to such opportunities as may more pertinently be presented as we proceed through the different branches of our subject.

THE COLLODION PROCESS.

In many existing treatises on this and other branches of the art, it has been the custom to introduce a vast variety of processes, which have been from time to time altered, improved, or modified by their authors. In our humble opinion, this course, whilst extremely valuable to those who have somewhat advanced, is of a most perplexing character to the student who may be commencing his attempts. We shall, therefore, employ the same method as we have adopted in all our previous pages, endeavouring to place before our readers plain and successive directions, that they may, in obedience thereto, gain a satisfactory conclusion. To avoid distraction of our arrangement, we shall omit mentioning the names of those individuals to whom photography is indebted for its advance; earnestly hoping, that if such peruse our pages, they will, with us, share the desire in which we write them—that of spreading, by all possible means, the elements and principles of knowledge to as great an extent as possible, in a disinterested and truly philosophic spirit. We shall give all the hints and practical details which our own experiments will allow; and only hope that our readers may reap any or every advantage from the facts which we have gathered from numerous sources.

Assuming that the student has provided himself with all the apparatus, chemicals, &c., which we have already mentioned, we shall suppose that, under our direction, he is about to take the portrait of a friend, or a *positive* picture of any stationary object. We commence with positive pictures, because, to the beginner, they afford immediate fruit of his early endeavours.

TO TAKE A POSITIVE PICTURE.

Our process naturally divides itself into the following operations; namely—

1. Cleaning the glass plate.
2. Coating it with collodion.
3. Rendering it sensitive.
4. Exposing it in the camera.
5. Developing the latent picture.
6. Fixing the picture.

The above have been arranged in the order in which they succeed each other; and neglect in carrying out each process individually, will, without the shadow of a doubt, bring inevitable failure as its result: whilst, if conducted in a quiet, persevering, and cleanly manner, success may most justly be expected to reward the operator's attempts. The glass plates are sold, of various sizes, by the instrument-makers; and the material should have a high polish—be perfectly free from specks or blemishes of any kind. For this reason common window-glass is rarely good enough; and a better kind, manufactured expressly for the purpose, must therefore be purchased.

1. *To Clean the Glass Plate.*—The methods proposed for this purpose are endless in number. We, however, find the following to succeed as well as any we have tried. Place the plate on a soft linen towel, and alternately rub each side till all free dust and dirt are removed. Then, by means of a little soft cotton wool, wash the two sides with a mixture of spirits of wine and liquid ammonia, in equal quantities; this will remove all extraneous solid matter: afterwards wash with distilled water. The plate being dried, must then be held by means of a finger and thumb placed at opposite corners, over a spirit-lamp, until the surface of the glass presents a brilliant polished appearance, and the whole becomes very hot: this removes a film of air which rests on every polished surface. We have never seen this plan recommended by any photographer; but have no doubt that in many cases it will prove a remedy for a common evil—that of the non-adhesion of the collodion film. We were first led to try it from long practice with Grove's voltaic batteries. The platina in such arrangements is always coated with a film of air; and unless this is removed, the nitric acid never comes in contact therewith. Having observed the effect of removing this aeriform coat in increasing the battery power, we tried it on the glass plate for photographic purposes, and have found, with many whom we have induced to try it, great advantage therefrom. After thus heating the plate, place it on its edges, so that it may rest at an angle against any support; and do not attempt to use it till quite cool, but do so immediately after it has regained the temperature of the surrounding

atmosphere, because another film of air or moisture will speedily form on its surface.

By such means a glass plate may be thoroughly cleansed from every kind of matter prejudicial to its employment for photographic purposes; presuming, of course, that the chemical nature of the glass is such as to present no other difficulty. We may here mention, that although glass, in a practical point of view, may be considered perfectly insoluble in any agent ordinarily employed to cleanse it—such is not strictly true. We are inclined to believe, that solutions of potash, nitric acid, &c., often employed by photographers to cleanse their glass plates, act in an unexpected manner in producing many of the difficulties which frequently present themselves. We are the more inclined to urge this point on our readers, from having found great difficulty in cleansing glass for the purpose of several experiments on polarised light, introduced in our previous pages. Even the mere mechanical action used in rubbing a piece of good glass, by means of a towel, silk handkerchief, chamois leather, &c., is quite sufficient to form minute lines, which are worked thus into its surface, and, therefore, render such uneven. Whilst visiting several mills in the north of England and Scotland, we were surprised to find in a large "doubling" establishment—that of Messrs. Coats, of Paisley—that thick glass rods, which have been employed as rollers, over which the cotton thread had to pass whilst being wound on the spindles, were cut through, in some places, to the depth of a quarter of an inch, by the soft cotton filaments. The two following experiments will impress this fact on the minds of our readers; and, at the same time, will show the necessity of great caution in rubbing or cleansing glass surfaces, whether in the form of lenses in the camera, or of plates intended to receive pictures on their surface.

Experiment 9.—Into a perfectly clean test-glass or wine-glass, pour a weak solution of carbonate of potass; then add a solution of tartaric acid—both being made by means of distilled water. Immediately after mixing the liquid, rub the sides of the glass, by means of the smooth end of a glass stirring-rod. After a short time, minute crystals of bitartrate of potass will be deposited only on those places which have been rubbed with the rod. Now, as we know that crystals always require an angular projection to cause them to be deposited on a surface, we may justly conclude that such has been produced on the inside of the glass, although by means seemingly inadequate to produce the effect.

Experiment 10.—Rub a piece of plate or window-glass repeatedly in the same direction, by means of an apparently soft towel. Allow it to cool from the production of heat which the friction will evolve. If the rubbed surface be then breathed on, a series of minute lines may generally be observed on holding the glass at an angle, and by viewing it by the light reflected from its surface.

We thus observe, that the polished surface of any body, no matter how hard it may appear, is really affected by others of a much softer nature, by rapid or peculiar mechanical action. As an expansion of the illustrations we have offered, we may state, that a piece of soft iron revolving rapidly, will cut a piece of hard steel as readily as a knife would a loaf of bread. We may, therefore, urge on our readers an excellent old saying of the Greeks—"hasten slowly"—as a motto to be held in mind when they are preparing plates for the camera.

One of the best tests of the perfect cleanliness of a glass plate, is the even condensation of moisture on every part of its surface. This indicates that its external condition is uniform in every place; and such is exactly the condition which an aspirant to success in the art should at all times endeavour to obtain.

After the plate is thus prepared, be careful to touch it in no part, except at those edges which are at the extremes of its diagonals. This rule should be observed carefully throughout all the subsequent processes: the only exception allowable, is that in which the plate must be held in certain positions during the time the collodion is poured on its surface—a process which we have now to enter upon.

2. *Coating the Plate with Collodion.*—The next step in our process is that of coating the cleaned plate with collodion. But before describing this, we shall give some directions with respect to arranging the camera, and thus of having it ready to receive the plate made sensitive by a subsequent process. The professional photographer generally has an assistant, who cleans the plate whilst the operator is getting the camera ready for it. As, however, we presume that our readers will work alone, we need scarcely state, that the camera should be adjusted before the plate is coated and made sensitive.

The person whose likeness is to be taken should put himself into a natural position, free from constraint, and in such a posture that all the muscles of the body may be, comparatively speaking, at rest. In our opinion, there is a vast deal more art in *sitting* to have a portrait taken, than in *taking* it. Almost every one experiences a degree of nervousness; and each determines to maintain a strict and grave deportment, which, by its affectation, increases, or at all events disposes to beget, nervous irritability. Hence, most persons complain that their "likenesses" are not like them; nor, indeed, can they be, when individuals practically determine, on such occasions, to assume airs and graces which, like ladies' best dresses and drawing-room furniture, are only used on "state occasions."

A support of some kind is required to maintain the head in its position; because the muscles of the neck are apt to become fatigued if a long "sitting" be necessary.—Contrivances of this kind are of various shapes; two of which are represented in the annexed figure. One of these (Fig. 152), as will be observed, may be attached to the back of a chair; whilst the other (Fig. 153) stands on its own pedestal. It will be found, in practice, that the latter is the most convenient, because it is easily adjusted to any position. The rest for the head is the curved portion at the top of each figure; and should be so arranged as to support the head of the sitter just behind each ear; and, of course, out of sight with respect to the camera, or they will be included in the portrait.

Fig. 152.

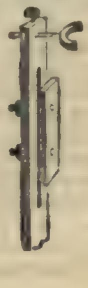


Fig. 153.

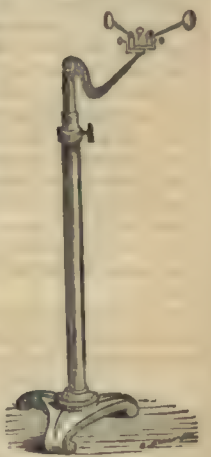

In arranging either of these supports, let them be employed solely as rests to support the head, and to prevent fatigue; and not as a framework, by which a rigidity of position would be induced, and stiffness of carriage promoted.

Having adjusted the position of the sitter, place the camera in front of him; and after removing the brass cap from the front of the lens, adjust the camera in such a position, that if you are taking the bust only, its image shall occupy the centre of the ground-glass plate. This is of course done by looking at the image on the ground glass; by shifting the camera to and fro; and focussing the lenses until a clear and distinct picture is observed.

In obtaining a good focal view, pay especial attention to the forehead and face, which of course form the essential points of the picture: and, in getting these correctly, the value of your lenses will at once be tested, and your full skill and judgment called into exercise; on which, in fact, success will depend. These points having been attended to, the ground glass is still to be left in the frame, so that the focus may be readjusted just previous to introducing the sensitive plate into its place.

Although a plate coated with collodion only, is unacted upon by light, still we shall presume that all the subsequent processes, except that of taking the likeness, are conducted in what is called a dark room. This room, in the language of photography, is considered to be a place into which not a ray of light of any sort, except of a deep *yellow* colour, is allowed to enter; such ray, as we have already remarked,* having little or no action of a chemical nature on the sensitive plate. The professional or amateur photographer often goes to considerable expense in arranging this "*sanctus sanctorum.*" We have had the good fortune to see a considerable variety, even from a room fitted with every convenience which science and means would permit, to one wherein a crazy four-post bedstead, covered with extremely ancient bed-furniture, did duty in the waggon of a travelling operator. Leaving the choice of position or place to our reader, we may remark, that an abundant supply of soft water running from a tap, a sink to carry away waste water, a large firm table, and complete absence of daylight, are the essentials of such a place. A sitting-room may be used in which the windows are completely closed from external light by means of thick brown paper pasted over them; and the water-supply may be that of a jug and pails, with such other contrivances, when circumstances render greater conveniences unattainable.

Of course light of some kind must be used to enable the operator to proceed. Some persons employ a tallow candle, others a low gas-flame; but both of these have a prejudicial effect on sensitive plates. In some instances a little daylight is admitted through thick orange-coloured glass. We have always preferred to use a spirit-lamp, charged with spirits of wine, in which *dried* table-salt has been dissolved. This affords a flame of a dingy yellow colour, perfectly inactive, from the absence of chemical rays—affording both sufficient light to work by, and also a ready and necessary source of heat when the plate has to be dried, &c., after fixing and washing. It is essential that the dark room should be kept scrupulously free from dust and dirt, otherwise it is more than likely that such will settle on the delicate collodion film, and spoil the plate. It is a good plan to wet the floor of the room, especially in summer-time, which will prevent the fine particles of dust rising as the operator moves to and fro.

A cleaned glass plate being held in the hands, the iodised collodion may be poured on it in the manner represented in the annexed engraving. The plate should be held quite horizontally in the left hand; the collodion bottle being placed over the centre, so that the liquid may spread evenly over every part until the edges are reached without its overflowing them. The object is to give a thin and perfectly even film to the entire surface of the glass; and when such is obtained, the superfluous collodion is to be poured off by holding the plate over a wide-mouthed glass bottle, so that its diagonal may rest on the neck. (See Fig. 155). The plate is then to be restored to an horizontal position for a few seconds, in order that the regularity of the film may be regained. This operation is one requiring both care and practice; and can only be successfully performed after the operator has had some little experience. It should, however, be done calmly, and without haste, to ensure good results; and it is advisable not to proceed further with any plate which does not present an even coating. Such are easily cleaned for another trial, in the manner already described.† Great care is to be observed in the mode of removing superfluous collodion after the glass plate has been covered with the liquid.

Fig. 154.

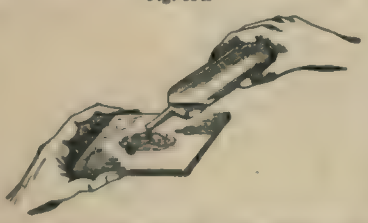

Fig. 155.

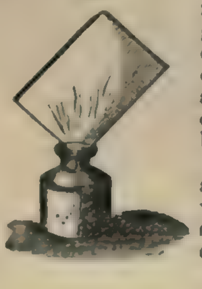


Presuming that an even, spotless, and otherwise perfect film of iodised collodion has been obtained, the next step is to render this sensitive to light, which we will now proceed to describe.

3. *To render the Coated Plate Sensitive.*—The choice of a "bath," as it is termed, for rendering a coated plate sensitive, has been a subject of great discussion amongst photographers; and almost every authority has propounded views and directions, which, from their diversity, are eminently qualified to perplex a beginner.

Although a middle course is at all times the safest in which to steer, it is most difficult to find that position. Some have recommended a proportion of nitrate of silver in solution as the most sensitising, which is much less than half the quantity that others consider essential to success. It has hence been found necessary to include various recipes in all of the works which have been produced that deal with this subject; and the recommendations, both scientific and empiric, which have thus been published, may safely be called "legion."

We confess to a difficulty in recommending any specific course to our readers; but we shall do well to inquire into those contingencies which may affect the best *formulæ;* and afterwards we shall endeavour to suggest, not *ex cathedrâ*, but in deference to the opinion of every one who may differ from us, as to what is the best course for the student to pursue.

The object which we have to attain, is that of making the coated plate sensitive to the action of the chemical rays of light; and this should be so effected as to require the shortest possible exposure in the camera to produce the picture. For this end, a salt of silver must be formed on the surface of the iodised collodion plate, which will meet our demands. The difficulty lies in satisfying all the conditions which are essential to success.

It would appear, at first sight, that the simplest mode of rendering a plate sensitive, would be that of immersing it in a solution of nitrate of silver, of any strength within certain limits; but it is found in practice, that the result of developing depends very much on the strength of the silver solution employed. Again, unless the "bath" is prepared by the addition of certain substances, the sensitive character of the film will be impaired, owing to a loss of a portion of its iodine when it comes in contact with the silver solution. Even the constitution (if we may so call it) of the film itself, in a mechanical point of view, may be either modified or injured by neglecting certain precautions.

The student must not suppose that we are presenting imaginary difficulties in his way. We are only anxious to anticipate circumstances with which he may have to contend; and thus by giving him preparatory hints, we hope to enable him to avoid both the Scylla and Charybdis of photographic manipulation.

From our own experiments, we recommend the following silver solution as an average one:—

Nitrate of silver	60 grains.
Distilled water.	2 ounces
Iodide of potassium	1 grain.

Dissolve the nitrate of silver first in an ounce and a-half, by measure, of distilled water; the iodide of potassium may then be dissolved in the remaining half-ounce of water. The two solutions should then be mixed and agitated together in a clean glass-stoppered bottle, and subsequently filtered through clean filtering-paper. This solution we have found to act well with good positive collodion. When, through repeated use, it has become replete with iodide of silver, a further addition of a solution of the nitrate of silver, without the iodide of potassium, should be made; and the whole is then to be filtered. A few grains of kaolin, or pipe-clay, may be added to neutralise an excess of free acid which will occasionally be present.

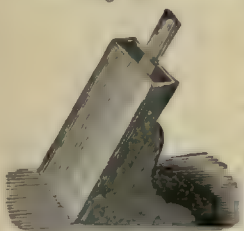
---

* See *ante*, p. 50.

† See *ante*, p. 146.

Many writers have recommended a less proportion of nitrate of silver; others have advised the addition of more iodide of potassium: some recommend the use of a little acetic acid and alcohol to such a solution. We can only state, that our own opinion is, that all these additions are, and have been, recommended to meet cases which may, or may not, occur to other experimenters. For instance, the nature of the collodion incessantly varies, by reason of the chemical changes to which it is subject; and with every desire to assist the beginner, we must state, that experience, patience, and watchfulness, are the sole guides or assistants on which he can at all depend. We shall, however, give a variety of recipes for these and other solutions which have been proposed by various experimenters, in another part of the work, leaving to the student the chance of trying each until an average of success attends his labours.

Fig. 156.



The solution having been prepared, it should be poured into an upright bath or trough, such as is illustrated in the annexed engraving. These are generally made of gutta-percha; but an upright glass, or porcelain trough, will answer just as well. The length and breadth, of course, must depend on the size of the glass. If the vessel be upright, and not oblique, it should not be less than half an inch wide. Sufficient silver solution should be employed as will nearly fill the vessel; and, of course, it should be in such a quantity as will cover the whole of the glass when introduced therein. Some operators use flat dishes for this purpose; but they run risks of spoiling the plate, owing to dust, &c., settling on the surface of the solution.

When an upright trough is employed, the plate should be placed in a frame, for the purpose of supporting it whilst remaining in the solution. This arrangement prevents the necessity of touching the plate, or of wetting the finger; and, as such, is conducive to cleanliness and convenience. One of these frames is represented on the outside of the trough in Fig. 156.

The plate having been coated with collodion, should, whilst still wet, be placed in the frame, and must then be *steadily* and *continuously* introduced into the silver bath. This should not be hastily done, lest the collodion film may be removed or injured; and no stoppage should be allowed, because that would produce a distinct and damaging mark on the surface. Of course this must be done in the dark room. After leaving the plate in the bath for about a minute, it should be gradually withdrawn; and after remaining a few seconds in the air, is again to be introduced, and may be left there for about two minutes longer. On removal, it should present an even opal appearance, and be perfectly free from spots, lines, &c., or otherwise it will be quite useless. The length of time during which the plate should be in the bath, depends on a variety of circumstances; and hence we have only mentioned an average, leaving to the experience of the operator to decide in special instances. It should then be placed in the dark frame, the lid of which should be carefully closed; and no time must be lost in transferring it to the camera, lest its sensitiveness may become lessened.

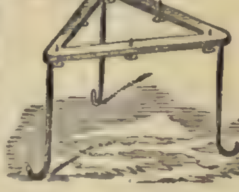
4. *Exposing the Plate in the Camera.*—The plate having been prepared, and placed in the dark frame, is now ready to be transferred to the camera; and in removing it, a cover of black cloth or velvet should be thrown over the whole before removal from the dark room. This precaution prevents any chance of a ray of light entering through any imperfection in the construction of the frame itself. The operator should again examine the image formed in the camera; for although only two or three minutes may have elapsed since he focussed his lenses, still persons are very apt to shift from their position; and therefore, of course, by so doing they will lessen the sharp appearance of their image on the ground glass. The sitter must be requested to remain perfectly still; and having arranged him in the most advantageous position, and refocussed the lenses, the brass cap in front of these should be put on to the tube, so as to prevent the ingress of any light into the body of the camera. The ground-glass frame is now to be removed, and the prepared plate must take its place. It is best put into position by lifting it up with the black cloth, which should be dexterously covered over the top of the camera, whilst the frame containing the plate is inserted in the slide. The lid or flap in front of the plate is now to be removed; and after again enjoining complete stillness on all present, gradually remove the brass cap in front of the lenses. The rays of light will now fall on the sensitive plate, and produce their chemical effect.

The student will expect that we should here give him minute directions as to the length of time during which he must expose the plate; but this it is impossible for us to do. The weather, both with respect to the amount and colour of daylight, has a great effect: then, again, the nature of the collodion employed, the colour of the face and dress of the sitter, and various other contingencies, render the question of great uncertainty. The same collodion used on two different days, or at different periods in the same day, may produce different results. As a general rule for the beginner, an exposure of from fifteen to thirty seconds may be adopted; and as he gains experience, he will soon be enabled to estimate the value of the different causes which tend to render a picture more or less perfect. We shall have to speak more fully of this presently, when we refer to the developing process. Presuming that the plate has been sufficiently exposed, the brass cap should now be replaced in front of the lenses; the flap is to be shut down in front of the plate; and the frame should be removed from the camera, so that the black cloth shall completely cover it. The frame, &c., are now to be removed into the dark room, for the purpose of development.

5. *Developing the Picture.*—The tyro will very likely imagine, that on removing the plate from the frame, he will observe the picture at once on the prepared surface. Such, however, never occurs: the plate presents, as near as possible, the same appearance after, as before, its exposure to light; and the latent picture must, therefore, be developed—that is, brought out into a sensible form by means of further chemical action. The philosophy of this process is easy of explanation: the iodide of silver, formed on the surface of the collodion when it was immersed in the silver bath,[*] has now become changed. That portion which has received the rays of light, will be differently acted on, by the addition of certain agents, to that on which no change has taken place by luminous rays. On pouring the developing solution on to the surface, this difference gradually becomes apparent as the picture unfolds itself on the glass surface. But we now proceed to the practical part of the operation.

The door of the dark room being closed, and only a faint yellow light employed, the lid of the frame should be removed, and the glass plate is to be carefully taken out, and placed, with the uncoated surface downwards, on a level stand, resting in a large porcelain or glass dish. Such an arrangement as this is represented in the annexed engraving.

Fig. 157.



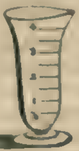
In the absence of a stand of this sort, two glass rods may be placed across the edges of the vessel; and on these the plate may rest; or even an inverted tumbler or wine-glass may be employed. The object is to keep the plate quite horizontal during the development, and to receive, in the dish beneath it, the superfluous developing fluid which will run from the plate.

---

[*] See *ante*, p. 148.

We would here urge on the operator to employ each vessel in his photographic practice for its special use only. By so doing, he will avoid any risk of mixing solutions, and of thus rendering them useless. Every chemical agent employed throughout the processes we have already mentioned, and are yet to describe, must only be brought together when wanted. If mixed carelessly, each solution, if present in only minute proportions, will certainly impair, if not destroy, the utility of any other. A place (or vessel) for everything, and everything in its place, should be a golden rule in photography.

Fig. 158.



The plate being thus arranged, the developing solution should now be poured on to it from a glass measure, similar to that represented in the annexed figure; and this should be done in a careful manner, so that the whole of the plate surface may be covered evenly with the liquid. The latent image will now gradually appear; and much care is required that the process is not carried too far, for fear of spoiling the picture. We must, of course, therefore leave the study of its indications to the judgment of the operator, who, although perhaps failing at first to arrive at the *exact* point at which development should stop, will eventually, after a few trials and failures, acquire the necessary experience. As soon as the picture is sufficiently brought out, all further action should be stopped by washing the plate well with cold water. This may be done by holding it cornerwise under a gentle stream of water running from a tap, or by pouring water in abundance from a jug with a narrow lip. It is extremely essential that this washing should be as complete as possible, so that every trace of soluble matter may be removed.—This being effected, the next step will be that of "fixing" the picture. But before we proceed to that, we must give our readers recipes for making the developing solutions to which we have been referring.

It will at once be perceived, by looking over the annexed list of solutions, that considerable latitude is assumed by various photographers. This is partly owing to the varying nature of the collodion employed; to the manipulation of the operator; and, in many instances, to the peculiar views of those who follow the art. We have, however, deemed it desirable, for the purpose of making our subject as complete as possible, to lay before the student ample opportunities for the exercise of his skill, judgment, and choice, with respect to solutions.

Developing Solutions for Positive Pictures.

Protosulphate of iron	40 grains.
Nitric acid	3 drops.
Acetic acid	30 ,,
Alcohol	20 ,,
Distilled water	1 ounce.

Or—

Protosulphate of iron	8 grains.
Acetic acid	1 drachm.
Nitric acid	2 drops.
Water	2 ounces.

6. *Fixing the Picture.*—The last-described process having fully developed the latent picture, it only remains to secure this from further change by the action of light. The result produced is simply that of removing every trace of those salts of silver which would become changed if white light were allowed to impinge on their surface.

There are two fixing agents which are chiefly employed by photographers, each of which has the power of removing the sensitive silver salts: these are the hyposulphite of sodium, and the cyanide of potassium.—The first-named of these salts was largely used in the early stages of photographic practice; but at the present time, the cyanide of potassium is mostly employed as a fixing agent; and as such, we have, from our own experiments, to add our testimony to its value.

The process of fixing is extremely simple. Either of the following solutions being employed—they are to be poured over the developed picture, and a portion is to be retained on its surface; or the plate may be dipped into a dish containing the solution, and be gently moved about in it. The soluble and changeable salts of silver are thus removed, and any risk of injury is entirely prevented when the picture is subsequently exposed to daylight. After remaining in the fixing solution for about two minutes, the plate should be abundantly washed by means of soft water. We always employ distilled water in the last washing; because river and spring water contain salts, which are left, to a minute extent, on the surface of the plate, and so dim its lustre, and, consequently, lessen the brilliancy and purity of the picture.

After the picture is thus thoroughly cleansed from every impurity, it may be left to drain, and to dry gradually. The usual method, however, is to hold it for a short time over a spirit-lamp or gas-flame; which, of course, speedily causes the evaporation of all moisture from its surface.

For all ordinary purposes the picture may now be considered finished, with the exception that it requires coating with a black varnish; which has the twofold effect of preserving the collodion film from injury, and of also increasing the effect of light and shadow. This varnish is sold by all photographic chemists; or it may be made by dissolving a little black asphalte in mineral naphtha. This should be poured on to the collodion surface, and left to dry. Some persons varnish the collodion surface with the best white mastic varnish, before applying the black coating.

Either of the following solutions may be employed to fix the picture. In that of the cyanide solution we have given considerable latitude; but it is advisable that the student should commence with a weak solution, and continue its use until his experience is sufficient to guide him safely in the employment of stronger kinds.

Fixing Solutions.

Hyposulphite of sodium	4 ounces
Water	16 ,,

Or—

Cyanide of potassium	6 to 12 grains.
Water	1 ounce.

It will be unnecessary for us to enter, at present, into a description of the modes of colouring positive collodion pictures, because we shall refer to this in a separate article. We may, however, mention a few causes which lead to failure in the early attempts of those unacquainted with the delicacy of photographic practice; and we shall discuss these in detail.

First, we may refer to the cleaning of the glass plate. This, we already have stated, is a matter of the highest importance, and sometimes one of some difficulty, because of the nature of the glass itself. The electrician is well aware, that no two circular glass plates, in the plate machine, will give off an equal amount of electricity when similarly employed, although they may be of exactly the same size. This is chiefly owing to the chemical constitution of the glass. Now, similarly in photography, the quality of the glass, to some extent, influences the photographic result; and such being the case, the operator cannot be too cautious in the purchase and choice of the plates he employs. In cleaning the plates, every precaution should be taken to prevent the presence of grease, grit, or dirt of any kind; and the least touch of the finger on any part of the cleansed surface, will most certainly produce an ugly spot at that place. Cloths, &c., used from time to time, gradually acquire grease and animal matter from the hands of the experimenter, and so communicate objectionable matter to the plate. Hence, an abundant supply of clean cloths is essential to success in the earlier steps of taking collodion pictures.

The collodion itself varies, according to the source whence it is obtained. Each maker considers his to be the best; but we advise the student, after making repeated trials, to keep to that which he finds to suit his purpose, and not to heed the various recommendations of his friends, or others, unless they are backed by decided proofs of superiority. Generally speaking, each maker maintains the regularity of the article he sells; and when once the student has so far succeeded in adapting his bath and developing solutions to one kind of collodion, he will only have the trouble of going over the old ground again, in attempting to suit his practice to the production of a new maker. Much, therefore, depends on making a first and proper choice of the collodion.

For the silver bath, a thousand-and-one advices and recipes have been given: indeed, their name is legion. The object of course is, that when the collodionised plate is immersed in the bath, its surface shall be made as highly sensitive as possible, and that each part should be equally so when compared with another. Sometimes the bath is too acid, and at others too alkaline. The former evil is remedied by the addition of a small piece of kaolin; and the latter by the addition of a drop or two of nitric or acetic acid. Now, without going far into practical chemistry, we may state, that a piece of litmus paper will turn red in an acid; and a piece of turmeric paper turns to a deep brown in an alkaline solution. These may easily be obtained; and by them the bath may at once be tested. The strength of the bath is subject to continual variations; because, every time a collodionised plate is introduced, a portion of silver is withdrawn, and a small portion of iodine is left behind. Now these facts must be borne in mind, because they necessarily influence the process to a great extent. Fogging is the result of an improper state of the bath; and from whatever cause such may arise, it is of importance that the remedy should be instantly applied. This tendency is generally removed by the addition of a small portion of nitric acid, so that the super-alkalinity of the bath may be destroyed, and a very slight acidity be produced. This is a point which, having named, we must leave to the judgment and skill of the operator.

Besides the alterations of the bath, produced by the causes to which we have referred, the student must bear in mind, that each time a plate is introduced, a small quantity of ether and alcohol is left behind. This produces a decided harmful effect in the end; and the only plan is to renew the bath entirely.

We may here state, that the silver can easily be recovered, in the form of chloride, from used-up baths, by precipitating with a solution of common salt. It may be reduced, by means of heat in a crucible, to the metallic state, if mixed with cyanide of potassium; which, however, is perhaps too troublesome a process to most of our readers. Photographic chemists and metallurgists, however, will purchase it at its commercial value; and this hint may therefore be of use to those whose means do not permit of extravagance in their photographic pursuits.

The developing solutions, like the sensitising bath, have been the subject of enormous variation in the proportion of their ingredients. We shall not enlarge thereon, because we shall only fall into the error of those who have preceded us, by giving advice for circumstances over which we can have no control, not being present to observe them. The student should watch the effect of the different strengths of the solutions he employs, and he will thus gain more knowledge by a few trials, than he could do by perusing any number of works on the subject.

In using the fixing solution of the cyanide of potassium, care should be taken that it is of not too great strength: it will be therefore advisable to use a weak one, and incur the expenditure of a little extra time, rather than to spoil the picture by employing one of greater strength for the purpose of speed. The motto of "hasten slowly," is, generally speaking, a piece of sound philosophy in the practice of photography.

Abundance of washing removes almost every chance of subsequent change in a positive picture. We strongly advise that the last washings should always be performed by means of *distilled* water.

In choosing the transparent varnish for the collodion surface, care should be taken that it is such as not to crack when dry. The same may be said of the black varnish used for backing-up the picture. Each of these can, generally speaking, be depended on when purchased of the photographic chemists, as they specially prepare these varnishes for the use of photographers.

Having thus detailed the processes and the difficulties, so far as obtaining positive collodion pictures is concerned, we pass on to give directions for obtaining negatives; and shall then describe the best modes of printing paper positives from them.

NEGATIVE PICTURES BY THE COLLODION PROCESS.

We shall now describe the methods which must be adopted to obtain negative pictures, or those in which the lights and shadows are the reverse of what we find in nature. The chief utility found in these pictures is, that they enable us to obtain any number of positive copies from them; and so, to a large extent, they increase the value of photographic processes, and approximate their application to a similar purpose of reproduction, as that obtained by the ordinary process of engraving.

The remarks, advice, and precaution which we have already afforded, are equally applicable in reference to this part of our subject. We, however, shall find, that in some respects, the materials employed, and the manipulative processes, vary from those which are followed in producing positive pictures; and it will now be our duty to point such out to our readers.

The plates are to be prepared with scrupulous care after the manner we have already stated, and are then to be coated with collodion prepared expressly for the purpose. This is generally sold under the name of "negative collodion," and contains more pure collodion, in each ounce of the liquid, than that employed for positive pictures. The following recipe for negative collodion is recommended by Mr. Hardwich :—

Purified ether, sp. gr. ·720	5 drachms.
,, alcohol, sp. gr. ·825 . . .	3 ,,
Soluble pyroxyline	3 to 6 grains.
,, iodide of ammonium . . .	3 to 4 ,,

Although we have introduced the above recipe, we still advise the purchase of the collodion by the student, as being the best course he can pursue.

After having obtained a good coating on the surface of the glass plate, it must be made sensitive by means of the silver bath; and in this, considerable variety of constitution has been recommended. The student must bear in mind, that a positive picture is required to give a distinct appearance of surface by light *reflected* to the eye; and this requires but a moderately thin coating of collodion. Now a negative picture must have depth and body, because its value and effects depend, in use, on the differences of tone produced by the light *transmitted* through it when paper copies are taken from it. Hence the various modifications required to produce these results in negative pictures during the preparation of the plates.

We annex some recipes for making the silver solution, or bath, which we have gathered from various sources; and the student will do well first to try them in the proportions named, which, however, he can modify as his experience permits, and circumstances require. We need scarcely repeat, that the ever-varying qualities of the collodion he may employ will frequently require such modifications in practice. A knowledge of this can only be gained by experiment under special circumstances; hence our duty cannot go further than to indicate, as complete direction to ensure constant success is entirely impossible.

Silver Bath for Negative Pictures.

Nitrate of silver	30 grains.
Iodide of potassium . . .	½ grain.
Distilled water	1 ounce.

This solution may be made by first dissolving the nitrate in a portion of the distilled water, and the iodide in the remainder. The two solutions may then be mixed together for use, and be filtered if necessary: or, the bath may be made by dissolving 200 grains of nitrate of silver in six ounces of distilled water. Into this place a collodionised plate, and leave it in the bath for twelve hours. Sufficient iodide will be removed from its surface to iodise the bath.

The plate being made sensitive, is then to be exposed in the camera, as when positives are being produced; but, as a general rule, the exposure should be of longer duration. Here, again, definite directions are impossible, because of the great variety of contingencies, such as weather, amount of light, temperature, &c., which have to be taken into account.

After due exposure, the plate is taken into the dark room to be developed. A different kind of solution is employed for this purpose, to that used in developing positives, although the process, so far as manipulation is concerned, is similar. Much care, however, must be taken to produce the best result. The process should be conducted slowly, and the effect of the developing solution must be constantly watched. When the operator conceives that a good depth of tone, and decision of light and shade is obtained, the process must be immediately stopped, and the plate should then be abundantly washed with cold water, preparatory to fixing. We annex recipes for various developing solutions as follows:—

Developing Solutions for Negative Pictures.

Protosulphate of iron . . .	1 ounce.
Acetic acid	12 drops.
Distilled water	1 pint.

Or—

Pyrogallic acid	5 grains.
Glacial acetic acid	40 drops.
Distilled water	10 ounces.

This solution requires filtration before use.

Another solution, as follows, may be used:—

Protosulphate of iron . . .	6 grains.
Glacial acetic acid	5 drops.
Distilled water	1 ounce.

Or—

Pyrogallic acid	4 grains.
Glacial acetic acid	60 drops.
Distilled water	4 ounces.

Our readers will here perceive the extraordinary latitude which is given in the choice of developing solutions. We must, however, repeat, that whilst we have employed each of the above, and scores of others, we do not venture to say which is the best, because the circumstances under which they are employed vary so much.

Presuming that the operator has succeeded in properly developing the picture, the next process, after careful washing, is that of fixing it. This is done by immersing it in a bath, or pouring over it a solution of hyposulphite of soda, which may be of the strength of—

Hyposulphite	3 ounces.
Distilled water	16 ,,

The picture must then be well washed in cold water, as already recommended, for positives, and so all traces of soluble matter must be removed.

As a negative plate has to undergo what we call comparatively rough usage, its collodion side must be protected in some way to prevent its destruction. This is done by coating it with a thin layer of varnish. The plate must first be gently heated, and the varnish is then to be poured on so as to cover the coated side on every part, most evenly. After the whole surface is covered with the liquid, the superfluous quantity should be drained off, by inclining one end of the plate until it is pretty well cleaned. The plate is then restored to its horizontal position, and left to dry, being carefully covered over to prevent dust or dirt falling on its surface.

The following varnishes have been recommended for this purpose, as suitable on account of their transparency and other qualities; but the operator can purchase those of a proper kind at the photographic chemists. The object to be kept in view is, to have a varnish which shall be transparent, and not liable to crack when it becomes dry.

Negative Varnishes.

Mastic varnish, diluted till of a thin creamy consistency.

Schnee's varnish, which consists of white lac dissolved in spirits of wine.

Copal varnish, of the consistency of thin syrup.

It sometimes happens that the depth of shade, in some negatives, does not sufficiently contrast with the lighter portions of the picture: the result is, that a good print can scarcely be obtained from such. To deepen those tones, we have tried baths or solutions of the bichloride of mercury, sulphate of iron, gallo-sulphate of iron, iodide of potassium, &c., of various strengths. A writer on the subject, in the *Photographic News* Almanac, recommends the following solution, which can be applied after the picture has been fixed: namely—

Iodine	1 grain.
Iodide of potassium	1 ,,
Water	1 ounce.

The picture is to be covered with this solution, and to be left for five minutes: the process may be conducted in daylight. A fresh development in the dark is then required, by means of the following solution:—

Pyrogallic acid	2 grains.
Glacial acetic acid	15 ,,
Distilled water	1 ounce.

This is to be poured over the plate a few times. To this solution may then be added a few drops of a twenty-grain solution, to the ounce of water, of nitrate of siver. This new solution is then to be poured over the plate. The iodine and pyrogallic solutions may be alternately used, until sufficient intensity has been obtained. The picture is then to be well washed, and afterwards varnished. The inventor of the plan states, that, as an intensifying process, it is to be preferred to that of the bichloride of mercury; and our own experiments confirm that view. The student will arrive at some successful results by taking the observations we have made, rather as a guide to his own experiments, than as final dicta. In hurried and unregistered trials with various solutions, we have occasionally hit upon successful results. We, however, do not recommend such a course to our younger readers; because, although permissible in those having experience, it engenders a careless habit in the beginner, which, of all things, is most to be avoided in scientific pursuits.

We have thus given, so far as we can judge, the most definite directions for obtaining good negatives. Our next course will be to show how such may produce positives by means of prepared paper of various kinds.

PRINTING ON PAPER FROM NEGATIVES.

We have stated, that the chief use to which negative pictures are applied, is that of producing an almost indefinite number of positive copies; and this is effected by means of sensitive paper, which the solid parts of the negative picture protect from the action of the chemical rays of light, whilst the lighter portions permit that influence to have a greater effect. The transparent parts of the negative allow the freer transmission of light, and thus we can obtain a picture presenting, so far as light and shade are concerned, an exact copy of the original. We regret to say, that all attempts to copy the natural colours of objects have hitherto failed. It has often been announced that such has been accomplished; but hitherto no success has actually been attained, although some approximation has been realised. A positive copy, although precisely the reverse of a negative original, yet has all its blemishes and excellences: hence it follows, that unless a good negative is employed, a good positive can never be printed from it. This fact the tyro in photography will do well to bear in mind, as it will induce care and caution in his attempts to produce the negative in the first instance.

In our earlier pages we gave some elementary experiments, illustrating the process of paper-printing. They were, however, necessarily of rather a crude character, because they were only intended as an introduction to photographic practice. We must now enter more fully into the minutiæ of the process, and so assist the operator in overcoming many difficulties which arise in its pursuit. We shall, therefore, examine each point in detail, so that the successive steps may be fully understood by all our readers. For this purpose, it will be proper that we should divide the process into separate heads; and in its pursuits, we must remind our readers of the necessity of care and complete cleanliness, as of the last importance. The following are the different points to which we shall separately call the attention of the experimenter:—

1. The choice of paper.
2. Its preparation.
3. The copying process.
4. The fixing.
5. The toning.

1. *The Choice of the Paper.*—Perhaps this is the most difficult, because it is the most uncertain, part of the whole affair. However much care is exercised in the selection, still some hidden defect is sure to appear in almost every specimen when it is submitted to the photographic process. At the present time, however, there are some paper manufacturers who produce an article intended solely for photographic use; and this, to a considerable extent, modifies the difficulties with which the photographer will have to contend. This is sold under different names, according to that of its maker. There is, however, a general title of French and English prepared paper. Either may be obtained, ready salted and albumenised, of the photographic chemist; and we shall, therefore, dismiss them without further remark, and devote some space for the benefit of those who may be unable easily to procure them. We may observe, that the two kinds of paper most esteemed by photographers, are the *Saxe* paper and the *papier Rive*.

In the manufacture of all sorts of writing-paper, numerous impurities, in a photographic point of view, are always present. The water employed in washing the rags, in reducing them to pulp, and in subsequent processes, contain common salt, sulphates, &c.; and in two cases within our knowledge, an appreciable amount of lead, or its sulphide, has been detected, owing to the impregnation of the water by that metal as it flows past the mines. Oxide of iron is almost invariably present, and no doubt exercises a decided effect on the results obtained in paper. We do not wish to multiply the difficulties which present themselves to the tyro; on the contrary, we prefer that he should know the chances of failure which may continually present themselves; and, by being forewarned, he may, by patience and care, be equally forearmed.

During the manufacture of paper, a portion of size or starch, and occasionally both, are introduced, for the purpose of giving a smoothness and evenness of surface to the texture. Our readers will be prepared to find that such matters have a decided effect on the nitrate of silver, which is the salt usually employed to sensitise the paper. A drop of the solution of that salt immediately produces a black spot on the hands, owing to the increased or peculiar action which occurs from the presence of animal matter. Generally speaking, animal or vegetable matter is always present in some form during photographic processes; but when so in circumstances beyond our control, it is often a source of great inconvenience.

With respect to ordinary sizing, there is no remedy; for blotting, filtering, or bibulous paper, are all objectionable; and the patent paper parchment which is prepared from these by means of sulphuric acid, is, from other causes, as unfit for photographic purposes.

We have found, that the best paper of an ordinary kind, and which is generally to be procured in most places, is common drawing-paper; that is, such as is used for lead-pencil drawing. All cream and blue-laid paper are utterly useless. The plain Bath or satin post may be employed; subject, however, to the difficulties and objections to which we have already alluded. The points requiring attention are—that the surface should be even; not too highly glazed; free from spots; and the paper itself as chemically pure as possible. These results can only be practically arrived at by repeated and careful trials.

Albumenised paper is generally employed by photographers, because the addition of the animal matter has a very good effect on the appearance of the positive, both during the process and after its completion. The mode of applying this, together with the salting process, we shall presently explain. Gelatine, starch, &c., are also used for the same purpose; but they are not so convenient in manipulation, or generally so successful in the result, as the white of an egg, which is nearly pure albumen.

Before proceeding to describe the preparation of the paper, we may state, that there are a variety of causes which, independent of the manufacturing faults, produce inconvenience to the experimenter.

In cutting, sorting, and packing writing-paper, &c., it necessarily passes literally through many hands; and each time it is fingered, it acquires, in some part, a portion of grease and common salt. Despite, therefore, of all possible care in selecting a good paper, these accidental circumstances tend to spoil it in some parts. Hence, we often find unaccountable spots, and what are called "stars" on the surface; these being generally brought to light during the fixing process.—For these we can offer no remedy; only let the operator be careful that he does not increase their number by his own carelessness.

2. *The Preparation of the Paper.*—If our readers can supply themselves with any of the different sorts of paper, ready salted and albumenised, the remarks we are about to make will be superfluous. But we should not be carrying out the general plan of our work, did we not prevent, as far as possible, the chance of our readers being left to their own resources, without any aid which we can afford them. We shall, therefore, give plain directions for the salting and albumenising process, and then deal with the modes adopted for making the paper so prepared sensitive to the action of light. The latter process is, of course, as equally necessary in its application to paper which may be purchased readily prepared, as for that which may be salted, &c., by the student at home.

The albumenisation and salting of the paper may be thus effected. Break a sufficient number of fresh eggs as to produce two fluid ounces of the white, which must be poured into a clean vessel as it passes out from the shell. Care should be taken not to mix any of the yolks with it. To the clear albumen so obtained add an equal quantity of distilled water, in which has been dissolved eighty grains of chloride of ammonium (sal-ammoniac). This salt is to be preferred to any other, for many reasons, and its action is generally to be depended on. Shake up the albumen and the water together, and when well mixed, pour them into a tall glass jar or bottle, and leave the mixture at rest for several hours. The clear liquid may then be poured into a plate or other flat receptacle, and after adding to it ten drops of liquid ammonia, it is ready for use. Then turn up one corner of a sheet of paper, so as to serve as a kind of handle, and placing the part next to the corner first on the surface of the liquid, gradually draw the whole of the paper so that each portion shall be equally moistened. If this be properly managed there will be no air-bubbles left on the paper surface. It may be left on the liquid for a few minutes, and is then to be hung up to dry in a moderately warm place. The object to be attained is that of an even coat of the albumen, so that when the paper is dry, each portion shall present a regular and even appearance. A good deal must be left to the tact of the operator: if, however, our instructions are carefully followed, there need be no risk of failure. Any quantity may be so prepared; and if it is properly dried, and kept in a dry place, it will remain without change for any length of time. We need scarcely say that it is not liable to alter by the action of light.

The sensitising process, or that by means of which the salted paper is rendered fit for the action of light, should be performed shortly before the paper is required for use, because animal matters, as we have already remarked,* have a spontaneous action on salts of silver. The solution may be as follows, viz.—

Nitrate of silver	80 to 100 grains.
Distilled water	1 fluid ounce.

This is to be poured into a clean glass or porcelain vessel; and a piece of the paper, prepared as we have described, is to be placed on its surface in the same manner as that recommended for its albumenisation, care being taken that no air-bubbles are left on the surface, and that no part be touched by the finger, except the turned-up corner. The paper may be left in the solution for a few minutes, and is then to be dried in a dark place, because, owing to the formation of the chloride of silver on the surface, it has become sensitive to light. Of course, this part of the process should, for such reasons, be entirely carried on by candlelight.

The strength of the silver solution gradually diminishes as each sheet is taken from it, and therefore an occasional addition of some more nitrate of silver, or of a strong solution of that salt, will be required. When the solution becomes of a brown tint, its colour may be restored by adding to it a small portion of pipe-clay. This is to be shaken up with the liquid, which can afterwards be filtered through some blotting-paper, if requisite.

3. *The Copying Process.*—To effect this successfully, a copying frame should be employed. It consists of an outer frame, which holds a sheet of plate-glass. The negative is placed on the glass with the collodion side next to the paper. The prepared paper is placed with its albumenised side next to the negative; and to keep the two in close contact, a back fits into the frame, and is secured by means of two cross pieces therein. Folds of blotting-paper, or soft cloth, may be placed between the paper and back of the frame, so as to press the paper firmly against the negative plate. This is of great consequence, because any crease in the paper would at once spoil the print, and produce general indistinctness of outline. The back of the frame is made to open and shut; so that whilst one part still firmly presses on the plate and paper, another part may be raised, and the progress of the printing examined.

We can give no definite directions as to the length of time required for exposure. We have already often remarked on this point. To illustrate this, we may instance the numerous experiments which have been made for the purpose of testing the question. In the morning of a summer day, in clear sunshine, the printing process has been effected in a few minutes; whilst after four o'clock, it has required an exposure of from half to three-quarters of an hour to produce the same effect. Occasionally we have noticed an almost entire suspension of actinic effect; but, a few moments afterwards, whilst the sun has been obscured by a thin cloud, the printing seemed to have gone on with increased vigour.

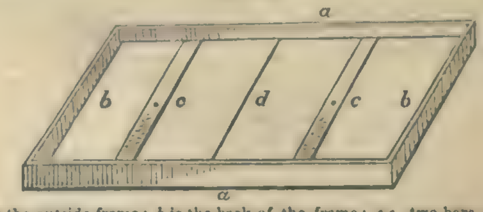
In the hope of giving something like an idea on this point, we have had collodion positives taken during every quarter of an hour, from ten in the forenoon, with little intermission, till six in the evening, in the early part of June, choosing alternately a clear sunshine and dark cloudy weather; and despite all attempts at uniformity in every circumstance, so far as manipulation and chemicals were concerned, our results entirely baffled any hope of affording constant rules.

Generally speaking, it is better that the positive should be over, rather than under-printed, because, when placed in the fixing solution, it undergoes considerable modification, and every part becomes of a lighter tint. Of course, much depends on the depth of shade, &c., in the negative, other circumstances being equal. We must therefore leave this point to the care and judgment of the reader, who will, by practice, arrive at something like certainty of result, and which experience alone can give.

During the printing process, the paper may be examined in the way we have mentioned, or a piece of the same paper as that in the frame, may be exposed under an equally thick piece of plate-glass, and the process of colouring be watched; unless so placed it will deceive the operator, because the glass of the frame exercises a retarding effect on the progress of the chemical changes.

A usual form of copying frame is illustrated in the following engraving:—

Fig. 159.



a is the outside frame; *b* is the back of the frame; *c c*, two bars, which fit into the sides of the frame, and so press the paper and negative together; *d* is a hinge, by means of which, either end of the back may be opened, so as to allow of the positive being examined during the progress of printing.

4. *The Fixing Process.*—Presuming that the positive has been properly printed, the next step is to prevent further action of light thereon, and so to render the picture permanent. This is effected by immersing it in a bath of hyposulphite of soda, which dissolves away all the unchanged chloride of silver. The proportions of the solution are as follow:—

Hyposulphite of soda . . .	1 ounce.
Distilled water	4 ounces.

On removing the print from the copying frame, it should be abundantly washed with cold water, which removes all substances soluble in that liquid. A solution of half an ounce of common salt, and a small quantity of bicarbonate of soda, is then made in a pint of water, into which the print is to be dipped, to free it from all traces of nitrate of silver and nitric acid. It should then be again washed in abundance of water, to free it from the soluble salts it may contain. The next step is to immerse it, face downwards, in the hyposulphite bath, in which it may remain for a quarter of an hour. It, however, should be continually examined, because the fixing solution has a tendency to destroy the distinctness of outline and gradation of shadow which gives the beauty to a good print. During this process, stains occasionally appear, which are owing to the accidental presence of free nitrate of silver. This should have been prevented by the salt and soda bath; or they may have been caused by carelessness in touching the print with the fingers. As hyposulphite of soda is a cheap material, it is better to use a fresh solution for every other picture. This plan often prevents the production of stains, and generally ensures good results.

It only remains that the print should be afterwards well cleansed from all hyposulphite of soda, which is done by placing it on the surface of clean water, and pouring a gentle stream on it for some time. The print is then left for an entire day in a vessel containing plenty of water, which should be occasionally changed. This having been effectually performed, the picture may be considered as permanently fixed.

5. *The Toning Process.*—We have as yet described what may be termed the ordinary process of printing: there, however, remain for us to mention various plans, by means of which the brilliancy of the positive may be increased. This is usually effected by means of a solution of chloride of gold, in the manner which we proceed to describe. We must specially observe, that great care is required to produce the best results; and the tyro must not expect, at a first trial, to arrive at perfection. For this reason we have deferred introducing the subject of toning until we supposed, by the practice of previous processes, some amount of proficiency had been acquired.

---

* See *ante*, p. 140.

We need scarcely observe, that nothing but a really good positive print is worthy of the toning process; and more than this, it should have been printed with that object in view. In giving instructions as to this process, we cannot do better than quote from the *Photographic News* Almanac, in which the writer lucidly points out each step. We can confirm, from our own experience, the statements which he makes; and shall presume that our previous instructions as to sensitising the paper have been fully carried out. The author of the paper referred to, says:—

"The printing should be effected as soon after exciting the paper as possible: considerable over-printing is generally desirable. The lights should be of a delicate lavender tint, and the shadows deeply bronzed, before the print leaves the pressure frame.

"The prints should be washed in two or three changes of water just before toning; and the final washing-water may have a little salt added. Long soaking in salt and water renders the toning more difficult. All the processes in connection with printing and toning, with the exception of the exposure, should be conducted in the dark, or in yellow light; and the most scrupulous cleanliness, as to fingers and dishes, must be observed. In regard to the latter, it is desirable that each one be kept to its own purpose, and never used for any other; and the utmost care should be taken not to put the fingers which have just touched the hyposulphite of soda, into the gold solution.

"Several different forms of the alkaline gold toning bath have been proposed, all of which have been practised with more or less success. We shall only refer to those with the results of which we are familiar, and can speak with personal confidence. The first is the process of Mr. Maxwell Lyte, with which most photographers are already familiar. It stands thus:—

"Chloride of gold	1 grain.
Phosphate of soda	18 grains.
Distilled water	*quantum suff.*

"The chloride of gold, and phosphate of soda, should each be kept in solutions of given strength—say one grain of gold to an ounce of water; they can then be well mixed in any quantity required for use, and diluted with sufficient water to float the prints easily. The only effect of using a large quantity of water, is to make the process of toning somewhat slower, which is frequently an advantage. Sufficient water tends, moreover, to secure regular toning. The prints should be kept moving, and prevented from sticking together, or red, imperfectly-toned patches will be the result. The water used for diluting the bath may be previously made warm, as it materially facilitates the process, especially in cold weather.

"The process of toning is more rapid in some cases than others; but in most cases, a few minutes—from two minutes to ten—is sufficient. It is, in all cases, desirable to allow the print to assume a little deeper tint than is required in the finished picture, as a little will be lost in the hypo fixing bath. If a sepia or brown be required, a decided purple tint should be obtained in the toning bath. If a decided purple be desired, then the tint in the toning bath should be black.

"For the phosphate of soda, the bicarbonate or biborate may be substituted, but in less proportions in regard to the carbonate especially, as an excess of it has a tendency to dissolve the size of the print, and, in some cases, even the albumen. Five grains will, therefore, be generally found sufficient; the only object being to neutralise the free acid in the chloride of gold.

"We have seen very fine prints produced by the toning process recommended by Legray; which is as follows:—

"Chloride of gold	1 grain.
,, ,, lime	1 ,,
,, ,, sodium; *i.e.*, common salt	1 ,,
Distilled water	4 ounces.

The treatment is similar to the first-mentioned; but as there is a strong bleaching tendency, it is necessary that the prints be considerably over-printed.

"The last process of gold toning to which we shall refer, is one published during the past year (1860), as being the suggestion of M. L'Abbé Laborde. We may mention, however, that its advantage had been pointed out some months before by Mr. Hannaford, who states, that a peculiarly rich purple bloom is secured, which is absent when any other salt of soda is used with the gold, with the exception of the citrate as proposed by Mr. Hardwich, which has a similar effect. Mr. Hannaford states, that it has another advantage, which the Abbé confirms—namely, that it may be used more than once; all other alkaline toning baths being useless for toning purposes after once being used for toning. The formula stands as follows:—

"Chloride of gold	15 grains.
Acetate of soda	7½ drachms.
Water	35 ounces.

"The solution becomes colourless by degrees, and, at the expiration of twenty-four hours, it is ready for use. On removing the positive from the printing frame, it is washed in two or three waters, to remove the free nitrate of silver; it is then immersed in the gold bath, where it must be allowed to remain not more than twenty-five to thirty seconds, when the bath is first used.

"If the gold bath has been used before, its action is slower. Experience will enable the operator to see, by the successive changes in tone the proof assumes, when he should remove it from the bath. If it be removed too soon, the proof assumes a disagreeable red hue after it is fixed with the hypo; on the other hand, if it be allowed to remain too long in the gold bath, the proof assumes a cold blue tint. Between these two extremes there are a variety of tones of sepia and violet, which can be secured by removing the proof at the proper moment. In proportion to the length of time the gold bath has been used, so we must prolong the toning until the required tint appears. The strength of the gold bath can be restored by adding fresh chloride of gold; but, before making the addition, we must take care that the solution is nearly colourless; for if the chloride of gold is not in combination, it will, like other chlorides, weaken the proof.

"In all cases the prints should be washed in two or three changes of water, and then immersed in the hyposulphite of soda; which, it is desirable, should possess a strength of at least twenty per cent., or four ounces to a pint of water. It is better used fresh each time, and should be neutral or slightly alkaline. Mr. Lyte recommends the addition of a little Spanish white, or chalk, for that purpose. Prints on thin paper are more rapidly fixed than those on thick; but they should not, in any case, be removed from the fixing bath in a shorter time than ten minutes. They should then be washed in several plentiful changes of water, within the first half-hour; and subsequently soaked and washed, so as to thoroughly remove all traces of hyposulphite of soda."

The above instructions will be of great value to all who desire to produce the best results obtainable in the printing process; and, as we have already observed, our own experiments affirm their useful and reliable character.

Having thus entered fully into the entire process of printing, &c., we trust that our readers will find no extraordinary difficulty in pursuing these experiments: and we shall now pass on to consider a variety of photographic processes; which, although not employed so universally as those we have minutely described—still, either afford interesting results, or, in an historical point of view, are not to be overlooked by us.

Our previous pages have been an exposition of processes which are universally adopted at the present time for likeness and landscape taking. Our limits have, of course, forbidden us to enter into every minute detail; and we must refer those of our readers who desire to make a special study of the philosophy of the processes, to the works of Messrs. Hunt, Hardwich, Price, and many others; in which they will find an almost exhaustion of the subject.

THE DAGUERREOTYPE PROCESS.

We shall now proceed to describe, in general terms, the process which, by the use of silver plates rendered sensitive by means of iodine, &c., gives similar results to those to which we have already alluded. We may, however, observe, that this mode of taking portraits, &c., has been, of late years, but rarely employed, for the collodion process has almost entirely superseded it.

We owe to M. Daguerre the first steps which were taken to render practically useful the fact that salts of silver are applicable to retain the impression of solar influences. It is true that Sir Humphry Davy and Mr. Wedgwood were well aware that copies of objects might be obtained by the agency of light; but those eminent men never proceeded beyond the threshold of their discoveries. M. Niepce and M. Daguerre, however, applied themselves to the subject; and the result has been, that every part of the civilised world has become familiar with the fact that light may be made a most valuable servant.

About twenty years ago, M. Daguerre discovered, that plates of silver, coated with iodine, were sensitive to the action of light, and that those portions so acted on, might afford a surface on which distinct pictures could be procured. This discovery produced a profound sensation in scientific circles; and the French government were so impressed with the novelty and value of the process, that they rewarded its discoverer in the most handsome manner. He had voted to him a pension of 6,000 francs; and France took to herself the credit of having given to the world one of the most surprising of discoveries.

That portion of the world which forms our native land, seems, however, to have been an exception; for a patent was taken out in this country, by which the employment of Daguerre's process was limited to one person and his licensees. If we compare the likenesses taken in the year 1840, with those of the present day, we shall certainly find that we hold the palm in every respect. This fact, however, must not deter us from doing justice to the valuable discoveries made by M. Daguerre.

One great objection which exists against this process is, that portraits, &c., produced by it, can only be viewed in one light, owing to the reflection from the silver surface. This is a source of considerable inconvenience, and, indeed, prevents any chance of representing some objects successfully.

We now proceed to detail each part of the process. In doing so, we shall not be so minute in our description as when speaking of the collodion process, for the reasons which we have already given. We may conveniently consider, separately, the following particulars, in the order in which we have arranged them :—

1. Cleaning the silver plate.
2. Iodising it, and exposing it to bromine vapour, &c.
3. Exposure in the camera.
4. The mercury process.
5. The fixing process.
6. The toning process.

1. *Cleaning the Silver Plate.*—We may here observe, that various sorts of plates may be employed, providing a surface of pure silver is formed thereon. Hence, copper, plated with silver by the ordinary method, or by electrotyping pure silver plates, or standard silver electrotyped over with pure silver, may be employed. In either case the surface requires to be highly polished; and the directions which have been given to secure this desirable result, are innumerable. We presume that a perfectly level plate has been chosen, free from scratches, &c. Its surface should first be roughly cleaned from oxide by dipping it into, or by rubbing it over, with a very dilute nitric acid; this removes a thin coat of the silver, but ensures, at the same time, more chance of success in the process of cleaning. The plate is then to be washed in plenty of cold water, so as to remove all trace of acid. This being effected, it may be polished by the following means :—Place the plate on a sheet of clean white paper, much larger than itself, and, by means of a pellet of the best cotton wool, which has been previously dipped in some of the best olive oil, commence rubbing the plate in a circular manner, from the centre to its outside. Having done this until the surface is covered with oil, dust over it some of the finest tripoli, and pursue the same plan of rubbing circularly, from the centre to the outside, for some little time. By such means all the coarse irregularities will be removed, and a tolerably level surface will be obtained.

The plan which we have adopted, after having given the plate the rough polish, is to wash it carefully with a mixture of equal parts of spirits of wine and liquid ammonia: this has the effect of dissolving and clearing away the minute portions of oil which would otherwise remain in the fine lines left on the surface of the plate; which, although invisible to the naked eye, may easily be detected by means of a microscope. After thus having cleansed the plate, it is to be held over the flame of a spirit or gas-lamp, which has the effect of driving away a thin film of air which always rests on polished surfaces, and of which we have already spoken.[*]

A little clean cotton wool, made into a pellet, is then to be moistened with spirits of wine. Having dipped it into some of the finest tripoli powder, the plate is to be rubbed with it until a dark jet-like appearance is produced: a dry pellet of cotton is then to be employed, to remove all trace of the powder. The last operation is that of buffing, or rubbing the plate on some velvet fixed tightly over a piece of wood. This is generally made, in shape and appearance, like a razor strop; and the plate is to be briskly moved, under pressure, to and fro on the surface of the velvet. By these means a brilliant polish is obtained; and, practically speaking, we may suppose the plate as fit for all subsequent processes.

We must here warn the tyro against carelessness in respect to the cotton wool, tripoli, and buffer, each of which are liable to catch small portions of dust, sand, or grit. Neglect of this is sure to afford a scratched and uneven surface on the plate. The smallest particle of any hard substance, repeatedly rubbed on a comparatively soft body like silver, produces an infinity of fine lines, and renders the plate useless. Our remarks on cleanliness, in a former page, have an equal application to the Daguerreotype process; and, indeed, too much care cannot be bestowed at each step of our progress.

When the operator has a lathe in his possession, much labour is saved by its use in the operation of polishing Daguerreotype plates, because both buffer and plate may readily be fitted in it. The action is much more regular than that obtained by manual labour, and there is less risk of producing a scratched surface through over-pressure on any part. We need scarcely add, that the time required for polishing the plate is also materially lessened.

2. *Iodising the Plate.*—After thus producing a clean and polished surface on the plate, it must then be made sensitive to the action of light by means of the vapour of iodine and bromine. In the earlier days of photography, iodine alone was employed; but the addition of bromine has many advantages, as we shall presently see.

The philosophical instrument-makers sell boxes expressly made for the iodising process. The student, however, will succeed very well by using a square box of about four inches deep, and a little longer and broader than the plate. The latter should be fixed in a frame so that it may be exposed with the silver face downwards. The frame itself may form the lid of the box. In the bottom of the box a glass tray must be placed, to hold the iodine, &c. A similar box will be required for the bromising process, if the operations are carried on separately. Of this, however, we shall speak more fully as we proceed.

To iodise the plate, put a small portion of iodine into the glass tray at the bottom of one of the boxes; and having fitted the silver plate, face outwards, in the frame, place it horizontally over the tray containing the iodine. The vapour which arises will reach the silver surface, forming an iodide of silver, which should be of a rose colour. The time required to effect this varies according to temperature and other circumstances; and so, like many other photographic processes, must be left to the judgment of the operator. As soon as the rose tint is obtained, the plate may then have its sensitiveness increased by means of the vapour of bromine, &c.; and such have been termed accelerators, from their power of rendering the subsequent processes more rapid of execution. After being iodised, the plate becomes sensitive to the action of light, but not to any great extent. It is, however, desirable that iodising should be carried on in the dark room; whilst it is essential that the accelerating process should be so conducted. Great care should be taken that as little as possible of the vapour of iodine and bromine should escape into the room, because such not only may have a generally prejudicial action on the plates, but also on various metals, chemicals, &c.; besides the personal inconvenience and injury which would occur to the operator.

---

[*] See *ante*, p. 146.

The accelerating effect is produced by exposing the plate, previously iodised, in another box, which has a glass tray, into which the accelerating solution is to be poured. The exposure is conducted in precisely the same manner as in the process of iodising, and a rich, but fuller, dark rose-red surface is obtained on the silver plate, which will then be nearly ready for exposure in the camera.

Accelerating Solutions.—A solution of bromine in water may be employed for this purpose; and it is made by adding some bromine to distilled water, and shaking the two together until as much bromine as possible has been taken up. One pint of this saturated solution is to be diluted with distilled water, until it presents a pale straw colour; and then poured, to the depth of half an inch, in the glass tray.

Another solution may be prepared by adding a few drops of hydrochloride acid to a drachm of bromine, which is then to be diluted with six ounces of distilled water.

By using the above solutions as accelerators, a rich red rose-colour is produced on the plate. The latter must afterwards be exposed again to the iodine vapour, until the silver acquires a very deep rose-red, or, occasionally, a blue colour, resembling that produced on steel when it has been heated to a temperature of between 600 and 700 degrees Fah.; and the iodising process is then finished.

An accelerator recommended by M. Claudet, has the advantage of preventing the necessity of a second exposure to the iodine vapour. A portion of it is poured into the glass tray of the accelerating box, and after the silver has been exposed to the action of the vapour for several minutes (even to the extent of half-an-hour occasionally), it is ready for the camera. The mixture consists of a saturated solution of iodine in bromine; which is easily done by adding as much iodine to the liquid bromine as it will take up. A bromide of iodine is thus formed, and as much of it is added to distilled water as will impart to the latter a full yellow colour. It is stated, that this plan is always to be depended upon; and it has one advantage for the tyro—which is, that he can scarcely err in its employment.

We must here point out a few matters by way of caution. The iodine should be spread evenly on the glass tray; because, wherever it is in masses, it will produce a deeper tint over that part. Care must be taken not to disturb the particles of iodine by hastily placing the plate on the top of the box, as this might possibly cause the air inside to be disturbed, and so drive particles on to the surface of the plate, where it would produce spots, and entirely destroy its fitness for subsequent processes.

3. *Exposure in the Camera.*—A sensitive plate having been produced, the next step is its exposure in the camera. On this head we have already made several remarks whilst directing the reader in conducting the collodion process. The same precautions and arrangements are required. The silver plate, however, is not so sensitive to the action of light as those of highly sensitised collodion. The time of exposure varies according to a variety of circumstances, each of which, as it presents itself, becomes the subject of annoyance to the operator, but yet adds to his knowledge and experience. We shall, therefore, not further deal with this part of the whole process, but refer our readers to the remarks we have made at a previous page.* We may, however, remark, that great care is required to prevent the effect called *solarisation*, which is due to over-exposure. This entirely destroys the contrast of light and shade, on which depends the beauty of all photographed productions. However, to prevent this, the operator must be well acquainted with the power of his lens, and the excellency of the plates and chemicals; matters which, of course, can only be gained by practice and experience.

4. *The Mercury Process.*—On removing the plate from the camera into the dark room, no picture will be observed on its surface; it must therefore be exposed to the vapour of mercury, which, settling on the face of the plate, rests on those parts which have been affected by the action of light. For this purpose a peculiarly shaped box is employed. In the lower part of it is a cistern, containing about two ounces of quicksilver; and in this the bulb of a thermometer is placed, which indicates the temperature of the mercury when heated by means of a spirit-lamp placed beneath it. This temperature should never be allowed to rise beyond 150° or 160° Fah. The plate is placed at an angle of 45° at the top of the box.

Presuming that a plate has been duly exposed to light, and is allowed to receive the vapour of mercury in the manner we have explained, we shall soon perceive that the parts which have been chiefly acted on by light, are most deeply brought out by the mercurial vapour, and every other part receives its due proportion, and produces a corresponding effect.

By these means the latent picture becomes developed; the effects of light and shade are produced on the surface of the plate, and a representation of the object copied is afforded, correct and brilliant, just in proportion to the care which has been exercised by the operator in each process, and in the actinic power of the light which has produced the picture.

5. *Fixing the Picture.*—The next part of the process is that of fixing the picture, and of so preventing the further action of light on the plate. The only thing required is to remove the remainder of the sensitive silver salt from the face of the plate; and this is effected by immersing the plate, when cool, in a solution of one part of hyposulphite of soda, to from six to ten parts of water. It should be left in the solution for a few minutes, and then must be abundantly washed with cold water. This is best effected by allowing a gentle stream, from a water-tap, to impinge on the plate: by these means all the soluble salts are completely removed. As, however, common water contains lime, &c., the plate should be finally washed with distilled water; and it may then be dried by holding it at some distance over the flame of a spirit-lamp. In drying, great care should be taken that no drops of water are left on the surface, as they would be sure to form spots. As the plate heats, the water has a tendency to run off from its surface; and an attentive operator will take advantage of this fact, so as to prevent the occurrence of spots, &c., thereon.

The appearance of all Daguerreotypes is remarkably improved by submitting them to the action of chloride of gold, after they are removed from the hypo bath. The contrast of light and shade is thereby greatly enhanced, and the brilliancy of the picture is of course increased. The process is very simple, and may be performed as follows:—

---

* See *ante*, p. 149.

6. *The Toning Process.*—After washing the plate, place it on a ring-stand, so that it may be quite level; and there is to be poured on it the following toning mixture, so that every part of the picture may be well covered. It is made as follows:—

Chloride of gold . . .	8 grains.
Distilled water . . .	4 ounces.

The salt of gold, having been dissolved, is then added to the following solution of—

Hyposulphite of soda . .	25 grains.
Distilled water . . .	4 ounces.

The two solutions, when mixed together, have a slight yellow tint, which, however, passes off. Some of this being poured on the picture, the heat of a spirit-lamp is cautiously applied beneath each part, until minute bubbles appear. In a short time, the improving effect of the toning process becomes visible, in the intensity and depth of contrast produced between the light and dark parts of the picture. The plate may now be left to cool, and the gold solution is then to be washed off, by means of distilled water, until the plate is perfectly cleansed. The spirit-lamp may now be used to dry it; and on this being carefully performed, the whole process may be considered as complete.

We have thus given a detailed account of the successive processes which enable us to obtain pictures on silver plates by means of the Daguerreotype process; but have omitted numerous modifications and improvements which have been from time to time suggested by various operators, because the process is rapidly becoming obsolete, in consequence of the greater value of, and the better results afforded by, the various processes on glass. It requires a considerable amount of care, and some photographic experience, to obtain even tolerable results; and, as we before remarked, the silver plate has the great objection of reflecting light, so that the pictures can only be seen at a certain angle. We are not aware of any photographer who professes to take portraits by this process at the present time; and therefore we have introduced the subject more as a curiosity, and as an illustration of the earlier attempts at picture-taking by the agency of light, than as one of any utility or profit to the experimenter.

We may conclude by stating, that if any of our readers attempt the process, and arrive at the very common results of obtaining "spoilt plates," such may be employed again by heating the surface to remove the mercury, and then by repeating the process of cleaning, according to the directions given in a previous page.*

THE CHROMOTYPE PROCESS.

This process is so easily conducted as to be at the command of any one, however slightly acquainted with science or experimental manipulation. It depends on the fact, that certain salts of chromic acid are easily acted on by actinic rays; and the most proper for the purpose is the bichromate of potass.

A saturated solution of this salt is made in cold water, in which any suitable-sized sheet of paper may be immersed. The salt will soon penetrate its pores; and the paper, after draining, is to be dried between folds of common blotting-paper. It will thus have acquired an orange-yellow tint, and it may be preserved for any length of time if kept in a dark place. It is used in exactly the same way as the positive paper (described at a previous page†) in the copying frame. The object is placed on the plate-glass: on this the chromatised paper; and the back of the frame is then fitted into its place; or the object may be simply kept in contact with the prepared paper, by means of a sheet of plate-glass.

The time required for exposure, of course, varies according to the chemical power of the daylight. The exposed parts should, however, present a dark-brown tint before the object is to be removed.

The process of fixing is remarkably simple. The picture is soaked for some time in warm water, so as to dissolve out any unchanged bichromate of potass. The paper will thus be rendered nearly white, or, at all events, of a light primrose colour, in those parts which have been shaded by the object copied; whilst the other parts present a dark-brown hue.

This process may be readily employed for copying any object whose outlines are well defined—such as lace, ferns, the shape of leaves, &c. Indeed, with a child's transparent slate, and a few sheets of paper, the botanist, and others, may copy a vast variety of objects; and, from the simplicity of the whole affair, it may afford an instructive and interesting amusement to young people.

THE CALOTYPE PROCESS.

One of the most ardent and successful of all those who have devoted their attention to photographic investigations, has been Mr. Fox Talbot. From the earliest days of the art he has continually made contributions to our stock of information; and to him we are indebted for a great variety of improvements on the processes proposed by other experimenters.

So early as the year 1839, Mr. Talbot communicated his views to the Royal Society, in reference to "the art of photogenic drawing, or the process by which natural objects may be made to delineate themselves without the aid of the artist's pencil." He also pointed out how such impressions might be fixed or rendered unchangeable by the further action of light.

The earlier attempts at producing and retaining photographic copies were but of a comparatively valueless character. The numerous causes of failure to which we have already so fully alluded, were only distantly guessed at; and the eagerness with which each new discovery was hailed, frequently prevented that close and philosophic examination into the chain of circumstances which gave them birth, or into the causes of failure, which almost invariably produced disappointment in those who attempted to repeat the experiments of others. We can well remember the obscure accounts which were published from time to time, in reference to the different processes, as they were given to the world. This, coupled with the various opinions held by discoverers, by no means assisted even the most ardent experimenter, but rather left him in what has expressively been termed "a fog." The mists of uncertainty, however, were gradually dispelled; and at the present time, photography stands out as one of the most complete applications, both in rationale and practice, of any which have been made of the various branches of science.

These remarks are here made, because we regard the calotype as the first elegant and complete branch of photographic manipulation. The discoveries of Daguerre were of great value; but those of Mr. Talbot at least equal them in that respect, and, in practical utility, often exceed them.

Having thus given a slight sketch of early photographic history, so far as it bears on our subject, we now proceed to detail Mr. Talbot's method of producing his calotype pictures; and shall introduce the subject in nearly the words used by the inventor whilst describing his earlier processes.

We may, however, impress on our readers the remarks which have been made in reference to the choice of paper. It matters not what process is undertaken in photography—the same chemical laws must be observed, and chemical changes must be looked for or guarded against.

The following, therefore, will guide the operator into what we may call the elements of the calotype process.

A proper paper having been chosen according to the general instructions we have already given, such is to be placed in a solution of nitrate of silver, dissolved in the proportions of—

Nitrate of silver . . .	100 grains.
Distilled water . . .	6 ounces.

In the manner described at a previous page.‡ The side so placed should be marked by means of a pencil, that it may thereby be easily recognised. The paper is afterwards to be dried in a dark place, and, if not immediately used (which is advisable), it should be kept out of the rays of the sun, or of diffused daylight. As, however, organic matters tend to decompose silver salts, even in the dark,* it is better that this paper should only be prepared in such quantities as may be consistent with the immediate requirements of the operator.

---

* See *ante*, p. 156.

† See *ante*, p. 154.

‡ See *ante*, p. 154.

The paper is then to be placed, with its silver side downwards, on a solution of iodide of potassium (hydriodate of potass), in the proportion of—

Iodide of potassium . .	100 grains.
Distilled water . . .	3 ounces.

By these means the iodide of silver is formed on its surface, which gives the paper a kind of primrose appearance. It is then dried, first being pressed between folds of clean white blotting-paper. In this state it is barely sensitive to the action of light; but the process should be conducted in a dark place, such as by candlelight, or in a dark room. This we may term iodised paper; and, if properly prepared, and all the precautions with respect to cleanliness, &c., having been observed, it may be kept for some time without danger of undergoing any very serious change. However, in our repetition of Mr. Talbot's experiments, we have found that the almost certain presence of organic matter in the size of almost every kind of paper, has a tendency to produce changes which eventually exhibit their effects in spots, &c., on the surface of the prepared paper, if such be made for any length of time before being used.

The reader will thus observe, that the calotype process depends on a formation of an iodide, in place of the chloride of silver, on the paper surface; and on this depend some of the peculiarities of Mr. Talbot's calotype process.

Before exposure in the camera, this iodised paper must be rendered more highly sensitive; and this is done by placing the prepared surface on a solution of—

Nitrate of silver . . .	100 grains.
Distilled water . . .	2 ounces.
Acetic acid	3 drachms.

To which is to be added an equal quantity of a saturated solution of gallic acid. We may here observe, that gallic acid is but sparingly soluble in water. Mr. Talbot calls the mixture the gallo-nitrate of silver. This solution should, whilst prepared in the proportions we have named, be only made in quantities required for immediate use, because it spoils by keeping.

After the iodised surface has been rendered sensitive by these means, the paper is to be dried; and this process should be conducted shortly before the exposure of the paper in the camera. It may be used with advantage in a slightly moist state, which somewhat facilitates the subsequent process.

The paper may then be used in the camera, in the manner already pointed out for the collodion and Daguerreotype processes; and the time of exposure will vary according to the sensitiveness of the surface, and the intensity of the light reflected from the object about to be copied. A latent image will thereby be formed; and this is to be rendered visible by placing the paper on, or by pouring over its surface, a solution of the nitrate of silver, acetic, and gallic acids just named. The photograph or calotype is thereby developed; and this should be done in a gradual manner. Sometimes the development takes place somewhat irregularly, and spots and stains appear. If the exposure has not been sufficiently long in the camera, the picture takes a considerable time before it appears; and, in such cases, the aid of a gentle heat may be called in. The picture may then be fixed by immersing it in a solution of—

Bromide of potassium . . .	100 grains.
Distilled water	10 ounces.

After which it is to be abundantly washed with water, and subsequently dried. By these means a negative is produced; and by dipping the prepared paper in a solution of iodide of potassium, a positive may be produced, providing the gallo-nitrate immersion has been adopted. After exposure in the camera, the gallo-nitrate solution is then used for development in the way already described, and the fixing process immediately follows.

Such is an outline of the earlier attempts of Mr. Talbot; which, however, have been modified by numerous subsequent experimenters. The same principles generally are involved, and the process is conducted more rapidly, owing to the more sensitive nature of the prepared paper.

The calotype process, like many others, is not so much in favour as that of the collodion, owing to the numerous details which have to be observed, and the tediousness of its manipulation. The effects, however, are very pleasing; and we may almost call it the most elegant and refined of photographic processes, when it is properly carried out.

THE WAX-PAPER PROCESS.

Amongst other materials which have been used as a photographic material, we may briefly notice that of waxed paper, which has the advantage of considerable sensitiveness, and of affording a pleasing effect when the picture is complete. This, like all other photographic processes, has been the subject of numerous modifications; and we shall, therefore, only give a general outline of it.

A thin kind of paper is to be soaked in the best melted white wax, until that substance is well absorbed into its pores. The waxed paper is then placed between folds of blotting-paper, and a hot iron is passed over the whole, so that the wax may be equally diffused, and any superfluity be removed. The paper, so prepared, is next placed in a bath of iodide of potassium, to which a little iodine has been added; and, after remaining some time, it is carefully dried. It is sensitised by means of a weak nitrate of silver bath, to which some acetic acid has been added; and if thus dried, it will keep for some time, provided it has been well washed with distilled water, to remove the superfluous nitrate from its surface.

The length of exposure in the camera varies from one minute upwards; and the latent picture is developed by means of gallic acid and nitrate of silver. The fixing is effected by a solution of the hyposulphite of sodium, and subsequent repeated washings in water. The picture may then be dried before a fire, and a hot iron should again be passed over it to equalise the wax in each part of the paper.

This plan is not much employed at the present time; and, like most others, has been superseded by the collodion process

THE ALBUMEN PROCESS.

A considerable variety of organic substances have been tried by photographers, as media by which the sensitive salts of silver may be retained on glass and paper surfaces. Amongst these, albumen has been frequently employed; and we have already drawn attention to one of its uses when speaking of positive printing-paper.† It has been applied with great success to glass plates; and some of the productions of French artists are extremely beautiful. Strange to say, few of the pictures produced exclusively by English photographers have arrived at such excellence.

Albumen, in this process, is used in place of collodion. The manipulation, generally speaking, is similar; great precaution, however, being paid to the delicate nature of the film, lest it should be injured. A picture prepared thus has a very transparent appearance; and the best of the kind we have seen are those of the blood globules, to which reference has already been made. Pictures by the albumen process are extremely valuable for use in the oxy-hydrogen microscope,‡ having a considerable transparency, and yet precision of detail. We shall now give full directions for pursuing the collodio-albumen process.

---

* See *ante*, p. 140.

† See *ante*, p. 153

‡ See *ante*, p. 63.

THE DRY COLLODION PROCESS.

Great inconvenience is felt by photographers in taking views by means of the ordinary collodion process, owing to the necessity of exciting the plate immediately previous to its being introduced into the camera; and numerous attempts have been made to prepare plates which would retain their sensitive condition for a length of time after they have been excited. These have resulted more or less successfully, but they still leave room for improvement. It was at first proposed to use a salt which would deliquesce, or absorb moisture from the atmosphere, and so retain the collodion surface in a proper condition for the camera. This plan was superseded by others, which seemed more convenient in practice. We can only refer to some of the latest improvements, which are, more or less, modifications of previously published processes: and we are indebted for the following *résumé* of recent inventions, to the pages of the *Photographic News* Almanac (1861).

THE COLLODIO-ALBUMEN PROCESS.

"The plates should be very carefully cleaned for this and all dry processes, and especial care taken that they are perfectly dry before coating with collodion. The quality of the collodion used is not of importance, so far as the question of sensitiveness is concerned; but for the better prevention of blisters, &c., an old or powdery collodion is desirable. The plate is coated and excited in the regular way, and washed thoroughly in a running stream, to remove free nitrate of silver. It is then coated with a solution, prepared as follows:—

" Albumen		2 ounces.
Distilled water		¼ ounce.
Iodide of potassium		10 grains.
Bromide of potassium		2 ,,
Liquid ammonia	about	20 minims.

"The iodide and bromide should be dissolved in the water, which should then, together with the ammonia, be added to the albumen, and the whole thoroughly beaten to a froth. When it has settled, the clear portion should be poured off, and kept in a bottle for use.

"The washed collodion plate is to be coated with this whilst it is still wet. After it has drained a moment or two, pour over its surface the albumen twice. The same albumen may be used for two or three plates; but after that, it is better to take a fresh quantity. The plate must now drain on one corner a few minutes; then dry it rapidly before a clear, bright fire, and make it quite hot. In this state it is not sensitive to light, and will keep for many months. To render the plate sensitive for use, it must be again immersed in a bath, prepared as follows:—

" Nitrate of silver	40 grains.
Glacial acetic acid	½ drachm.
Water	1 ounce.

"After taking the plate out of the bath, drain a moment, and then wash well under a stream of water. A plate well washed always keeps longer, and develops cleaner, than one washed insufficiently. After washing, drain, and place it on blotting-paper to dry. The plate may be dried artificially; but will do so spontaneously in about ten minutes.

"The plates will keep ready for the camera two or three weeks in summer, and as many months in winter; but it is better to use them fresh.

"The development of the latent image is the most important operation in this process. It is slow; but, on that account, very manageable. If the plate is well exposed, and free from blisters, there is no doubt of getting a picture. There are two methods of development; with pyrogallic acid and with gallic acid. To develop with pyrogallic acid, take the exposed plate, and place it on a levelling-stand; pour a little water over the surface; then take a sufficient quantity of the following developing solution:—

" Pyrogallic acid	2 grains.
Glacial acetic acid	½ drachm.
Water	1 ounce.

And pour it over the plate repeatedly. When the sky and high lights appear, add a few drops of a ten-grain solution of nitrate of silver. This will bring out all the details of the picture; but when held up to the light, it will appear weak and transparent. In this state more silver should be added, until sufficient intensity is gained.

"During the development, it is more than probable that the surface may be marked by streaks or stains, or a deposit may cover the whole plate. If this should occur, stop the development; wash with water; and with a piece of fine cotton wool, rub away these defects, and go on again with the development; the horny surface of the albumen allowing this to be done without fear of damaging the negative. This is the great advantage the process has over every other. The plate can be developed for hours or days; because, though a deposit falls, it can be wiped over and over again. This is an immense advantage when the picture is under-exposed, as it can be frequently brought out by long development.

"To develop with gallic acid, take the exposed plate, and put it, face upwards, into a glass or other dish, with a sufficient quantity of a saturated solution of gallic acid to cover it. When it has remained five or ten minutes, add a few drops of a ten-grain silver solution, and mix well in the dish; the picture will gradually appear. When all the details are out, add more silver, till the development is complete.

"Whichever process of development be adopted, great care is required to attain just the proper amount of intensity, and no more. In all processes where albumen is used, the real printing intensity is much greater than it at first appears, owing to the light-resisting colour of the deposit. There is great danger of over-development, as some photographers are not content until the sky is quite black; at which time, in an artistic point of view, the picture is quite ruined.

"The picture is fixed with hyposulphite of soda, in the proportion of five or six ounces of the salt to the pint of water. Cyanide of potassium would act rapidly on the organic deposit, and is therefore unfit for use."

THE FOTHERGILL PROCESS.

From the same authority, we quote the following particulars of a modification of the Fothergill process; so called after its inventor.

"For coating the plates, take of old iodised collodion, containing one grain of a bromide, in addition to four of iodide, one part; and of a newly iodised collodion, containing iodide only, one part. The glasses must be carefully cleaned, and quite dry when coated: a thirty-five grain nitrate bath, with a very slightly acid reaction, is the best sensitising solution. The plates, when excited, must be washed in a limited quantity of distilled water. A solution is then required; prepared as follows:—Of albumen, from fresh eggs, one ounce; of water, three ounces; of the strongest liquid ammonia, a few drops to each ounce of the preparation; and also a few grains of citric acid. The plate is coated with this preparation, which is left on it a few minutes; it is then to be thoroughly washed in water, and dried. Plates so prepared are very sensitive, and possess good keeping properties."

We have chosen the two processes above described, because they are comparatively easy of prosecution. A variety of substances, of a vegetable kind, have been employed as preservatives; such as linseed, malt, glucose, &c.; but our limits forbid us entering into special details respecting them.

Our readers will perceive, that many precautions have to be observed to ensure successful results; and their patience and perseverance will doubtless be well tested. At the same time, a really good negative is an ample reward for all the pains we can bestow; whilst an inferior one is, at all times, valueless for printing purposes.

PHOTOGRAPHIC ENGRAVING.

The usual process of copying from negatives is necessarily somewhat slow, and therefore greatly limits the production of paper positives. A great variety of attempts has accordingly been made, the object of which has been to produce blocks, on which photographic pictures could be engraved, and printed from.

Some of the earliest experiments for this purpose were made on Daguerreotype plates. These were etched out by chemical means, or electrotyped, so as to present an uneven surface, which would afford the effects of light and shade when engraved from.

One of the best prints which was made by this process, was produced many years ago, by Mr. Grove, at the London Institution; being an outline of that building, obtained from a Daguerreotype. However, no great success attended the efforts then made.

Mr. Fox Talbot and others have, since then, made considerable advance in this department of photographic practice. Pictures have been transferred to stone and wood; and, from these, engravings have been produced. We shall confine our remarks to two processes; the first being that of photozincography, for an account of which we are indebted to the *Photographic News* Almanac; and M. Pretsch's process, which the inventor kindly explained to us himself, and the whole of which we have frequently repeated.

The photozincographic process is described as follows:—

"The most successful method of carbon printing, is that perfected by Colonel Sir Henry James, R.E., Director of the Ordnance Survey of Great Britain; which has led to the most important results, both in an artistic and economical point of view. The singular advantage which this art possesses, consists in the fact, that we can now produce authentic copies of any of the numerous rare manuscripts, which are carefully preserved in different parts of the world; and print any number of copies of them that may be required, at a cost which will not exceed one penny for a folio sheet, and this without ever touching the original document; or, if required, without even being in the same room with it, provided we have a hole in the wall, to place the lens of the camera in.

"Photozincography is the name given to this process, which is the art of producing a photographic *fac simile* of any subject; such as a manuscript, a map, a line engraving, and transferring the photograph to a zinc plate; thereby obtaining the power of multiplying copies in the same manner as is done from a drawing on a lithographic stone, or on a zinc plate.

"The process is based on that first suggested by M. Aser, of Amsterdam; viz., the obtaining a photographic picture on paper prepared with the bichromate of potass; washing off the unchanged salt; inking the image left on the paper with photographic ink; and then transferring the same to a prepared zinc plate, from which any number of impressions may be printed.

"The steps to be taken to obtain this important result, are—first, to produce a collodion negative on glass, in the usual manner, of the document to be copied; this negative may be identical in size with the original, or larger or smaller, as may be most desirable. The greatest care is required in obtaining this negative perfect, as any defects it may contain, will necessarily be reproduced in the copies. The lenses employed must be in due relation with the size of the object copied, so as to avoid distortion.

"The negative will require to be intensified, in order that whiteness of the paper may be reproduced in the positive. This intensity is readily obtained by immersing the fixed negative in a saturated solution of bichloride of mercury, washing it with water, and then putting it into a solution of commercial hydrosulphate of ammonia; one part to ten parts of water.

"In this manner the ground of the negative is rendered extremely dense, without the clearness of the details being in the least affected. When dried and varnished it is ready for use.

"With this negative we proceed to obtain positives on paper. The quality of this paper is a point of much importance; the best is that known as 'engravers' tracing-paper.'

"A solution of gum-arabic is made by dissolving three ounces of the gum in four ounces of water.

"Boiling water is saturated with bichromate of potass; and two parts of the solution is mixed with one part of the gum-water, both being kept at a temperature of 200° Fah.

"The tracing-paper is evenly coated with the hot mixture, by means of a flat camel-hair brush, and dried; it is then exposed to light, under the negative, in the usual way. The time for printing may vary from two minutes in the sunshine, to ten minutes in clear diffused light. If a good image is not obtained in that length of time, the operation had better be deferred to a more favourable opportunity. The period of exposure is determined by the appearance of the print; when all the details have become distinctly impressed, it may be removed.

"The next thing is to coat the entire surface of the print with an even and thin layer of a greasy ink, which may be composed of the following ingredients:—

" Middle linseed oil varnish . .	4½ ounces.
Wax	4 "
Tallow	½ ounce.
Venice turpentine . . .	½ "
Mastic resin	¼ "
Lampblack	3½ ounces.

"A portion of these is dissolved in turpentine sufficient to form a thin cream, which is applied to the surface of the positive print with a brush.

"The turpentine is allowed to evaporate for half-an-hour, and the positive is then floated, face upwards, on hot water for a few minutes; then removed, and laid, in the same position, on a porcelain slab.

"The surface is then gently rubbed with a sponge, dipped in warm gum-water, when the ink readily leaves the surface at those parts which have been unacted on by light; while it adheres tenaciously to the details of the image.

"As soon as the lines are quite clear, the print is placed on a flat dish, and washed, first with warm, and finally with cold water. When dry, it is ready for transferring to zinc or stone.

"There are two methods of transferring to zinc, varying according to the quantity of ink in the photograph.

"If a very small quantity has been applied on account of the closeness of the lines in the subject, the print is transferred by the anastatic process.

"If a larger quantity of ink has been applied, the process is different.

"The positive is laid for ten minutes between sheets of paper, damped as uniformly as possible with water; it is then laid face downwards on the plate, covered with two or three sheets of paper, and passed once through an ordinary lithographic press. The sheets of paper being removed, it is damped at the back with gum-water, till its adhesion to the plate is so lessened that it can easily be pulled off. After the transfer has been gummed, brought up, and etched, the ink is cleared off with turpentine, and the design is rolled up with printing-ink. Impressions can then be taken from it.

"The quantity of ink necessary to be applied to a photographic positive, to make a successful transfer to grained zinc, is greater than that which is necessary for stone; and the anastatic process requires the least of all.

"The action of the warm water in which the positive is immersed on the insoluble gum, is to cause it to swell; and the ink which overlies the lines formed of insoluble gum, expands likewise. It is evident, therefore, that if the subject photographed be of a close nature—as a fine engraving—the amount of enlargement of the inked lines may be sufficient to bring them into contact while the print is in the water; and when they have once coalesced, they will not separate again when the gum shrinks in drying, and there will consequently be a continuous shade of ink instead of lines. In such a case, the quantity of ink applied should be as small as possible; and to enable a light but even coating to be laid on it, must be thin. As a consequence of the small quantity of ink used, the transfer must be made on a smooth plate by the anastatic process; because, to make a successful transfer to a grained plate or stone, a larger quantity of ink is necessary. On the other hand, as impressions taken from a grained plate or from stone, are, as a rule, better than those from a smooth plate, and as a larger number of good impressions can be struck off if the subject photographed be so open that there does not appear to be any likelihood of the lines coalescing in the water, it is better to apply the ink in greater proportion to the print, as a certain quantity is indispensable for the employment of the latter mode of transfer. By the application of this process to the reduction of the plans of the Ordnance survey, an immense saving of time is effected; while the total money saving will amount to no less a sum than £35,000 on the cost of the survey."

Having thus given our readers the above account of the photozincographic process, we shall now proceed to describe that of M. Paul Pretcsh; which, as already observed, we have repeatedly examined in all its details.

M. PAUL PRETCSH'S PROCESS FOR ENGRAVING BY LIGHT AND ELECTRICITY.

PERHAPS one of the most ingenious and successful inventions which has yet been made in attempting to adapt photography to the purposes of the engraver, is that invented by M. Paul Pretcsh, formerly manager of the Imperial Press at Vienna. That gentleman courteously explained the entire process to us; and we shall give our readers a general outline of it.

The inventor avails himself of the fact, that animal matter, combined with bichromate of potass, is peculiarly acted on by light, and becomes thereby considerably hardened. A mixture of good glue or gelatine is made with a solution of bichromate of potass, aided by the application of heat. It is of such a consistency as to become solid when cool. Whilst in the liquid state, solutions of nitrate of silver and iodide of potassium are added to it; and after the whole has been well incorporated together, the liquid is poured on to a clean glass plate, and allowed to cool in a dark place.

Presuming that an engraving is to be copied, it is to be placed, face downwards, on one of these prepared plates, and pressed closely on the glued surface. This is best effected by the copying frame referred to, and illustrated, in a previous page.* It is then to be exposed in the usual manner, varying from a few hours in direct sunlight, to a day or two in diffused light. On removing the plate from the frame, it will present no great visible change, or, at all events, its surface will still be perfectly level, even if some effect of shadowed outlines may be perceived. It is then to be immersed in water, or, as we believe the inventor recommends, a solution of common salt in water. An immediate effect takes place: those parts which have been exposed to solar action retain their previous condition; whilst those which have been shaded by the dark part of the engraving from the action of light, immediately rise up beyond the ordinary level, and form a series of *raised* lines, exactly resembling the shaded lines in the original. The glue surface, therefore, assumes exactly the opposite condition of that of an engraved plate in which the shaded portions are *hollow* lines. The plate is then dried; and when again each part has become firm, a cast is taken from it by means of any suitable substance, such as plaster of Paris, which, of course, produces an *intaglio* impression. From this a cast is taken by means of gutta-percha, &c., which becomes the mould, from which a solid engraved copper-plate may be obtained. For this purpose the electrotype process is employed; to explain which, we may observe, that a current of voltaic electricity passing from one pole of a battery through a metallic solution, conveys at the same time portions of that pole to the other extremity or terminal of the battery. A galvanic battery consists of a sheet of zinc, and one of copper, silver, or platina. To each metal a wire is attached, and the two sheets of metal are placed in a jar, into which acid and water are poured. So long as the two metals do not touch each other, or the wires attached to them are apart, no action takes place in the battery. But on contact being made, then a current of electricity passes from the zinc, through the liquid to the copper, and thence by the wire, back to the zinc. If, however, the two wires are placed in another vessel containing a solution, say of sulphate of copper, then the electricity will pass from the wire attached to the copper-plate, through the solution, to the wire proceeding from the zinc plate, and the latter wire will receive continually the metal from the opposite one, till it is entirely dissolved away. If the gutta-percha mould is first blackleaded carefully so as to make it a conductor of electricity, and it is then attached to the wire from the zinc end of the battery, whilst a copper-plate is hung from that wire proceeding from the copper end of the battery—both being immersed in a jar containing a solution of sulphate of copper, and dilute sulphuric acid—the mould will be completely covered with the metal transferred from the plate by the electric action; and in the course of twenty-four hours' action, a complete copper copy will be produced. This is next gently removed from the face of the mould; its edges are trimmed; and it may then be employed in the printing-press, in exactly the same manner as an ordinary engraved copper-plate.

It will be perceived that, by this curious process, a complete and perfect engraved copper-plate may be produced by the sole action of light and electricity; and viewed in a philosophical point of view, it presents the most astonishing application of two forces with which we are acquainted.

For the sake of simplicity, we have only supposed the case of the copying of an engraving. Photographs, &c., can, however, be easily reproduced by the same means; and thus an exact copy of any object can be almost indefinitely produced. The inventor, however, finds, that, owing to the softness of copper deposited by the electrotype process, not more than six or eight hundred copies can be printed from one plate. Any number of plates, however, may be produced from the original mould. We have seen numerous specimens of engravings so procured; and have no hesitation in pronouncing them to be of the greatest accuracy and perfection in their detail and general effect. The ingenious inventor has applied the process to a variety of purposes; amongst which we may mention that of producing engravings from personal photographs; by means of which, linen or cotton may be marked with the likeness of the owner, intead of by the ordinary plan of marking-ink. Our readers of the fair sex will instantly appreciate this application, because it prevents that constant interchange of the ownership of property, to which the laundry-women of our large towns are so prone. Similarity of initials is common enough; but a photograph on wearing apparel at once stamps an unerring title as to the proper right of possession.

We are not aware that this invention has received that encouragement which its value deserves. Several illustrated works, however, have been published, in which the cuts have been produced by the process. Its value greatly consists in the accurate reproduction of natural scenes, &c., represented by it.

STEREOSCOPIC PHOTOGRAPHY.

THE stereoscope is so well known as not to require any particular description on our part. It gives to the eye the effect of solidity from two pictures, placed in a proper position, the images overlapping each other. We have already entered into an exposition of the principles of the laws of vision;† and our remarks on the cause of single vision by two eyes, may be taken as descriptive of the effect of the stereoscope. The particular form of the instrument varies according to the peculiar method of construction of each maker; and into such we shall not enter, but rather confine ourselves to the method of taking stereoscopic pictures, and the instrument required for that purpose.

---

* See *ante*, p. 154.

† See *ante*, pp. 44 and 49.

In a single camera, the rays of light passing from an object to the ground glass or sensitive plate, do so exactly as occurs when any object is seen by one eye. If another camera be placed next to the first, the rays will not fall exactly to the centre of its plate, because they arrive at two different angles from the source. Again, if an object, at a short distance from the eye of the observer, is viewed alternately by each eye, it will not appear in the same position as it would if viewed by both eyes simultaneously. The distance between the two eyes, of course produces a separate angle of vision for each; and hence the right eye can see further to the left than can the left eye; and, *vice versâ*, the left eye can see more to the right of any object.

Now stereoscopic pictures are always taken in duplicate, each at an angle varying with the other, as the angle of vision of the two eyes differs. It follows, therefore, that either two cameras must be employed, or that, if the picture is taken by one camera, then the instrument must be successively placed in two different angles to take the picture in a proper manner. An inspection of any stereoscopic print will illustrate the remarks we have here made; for it will be found, that one either exceeds or falls short of the other in the representation of the width of its field of view.

In practice, a double camera is always employed; for the operator, having the two instruments arranged permanently at the proper angle, has no trouble in the mechanical part of the process. Besides this advantage, the person desiring a likeness has not to undergo the fatigue of a double sitting, and the chance of placing the head and body in such a position as would be required to produce a second and corresponding one to that first procured by the single arrangement.

The entire manipulation, beyond the management of the camera, is exactly the same, in all respects, as that we have described under the collodion process; two plates being employed, or rather one plate, on which two pictures are produced.

The stereoscope has done much towards popularising the art of photography; and the favour with which the simple instrument has been received by the public, has induced the invention of a great variety of arrangements, by means of which, a number of pictures may be successively viewed by one or more persons. The pictures are generally mounted on an endless band, between two stereoscopes placed opposite to each other; and thus the number of pictures is limited only by the length of the band, or the size of the whole arrangement. A handle, affixed to the roller on which the band revolves, brings the objects successively in view to either stereoscope.

MICROSCOPIC PHOTOGRAPHY.

Some very interesting results have been obtained by applying the photographic process to obtaining pictures of microscopic objects. This is easily effected by receiving, either through or without the eye-piece of an achromatic compound microscope, the image of the object on a plate by means of the usual collodion process. In fact, the lenses of the microscope answer in place of the lens of the camera: the plate, however, must be so arranged as to be entirely protected from external light. This is easily done by placing it in a small dark box at the end of the eye-piece, from which the image proceeds to the prepared plate.

Such pictures can afterwards be submitted to the microscope, and may of course be magnified to any desired extent. One great advantage arising from this use of photography is, that perishable objects can be copied exactly as they appear at any moment, and so all their peculiarities of construction or constitution may be permanently retained; and if negatives are taken, any number of copies can be subsequently produced either on glass or paper.

Perhaps the most interesting kind of photographs of this kind, are those which have been taken of the blood globules of animals, of which we have already spoken in connexion with the oxy-hydrogen microscope.* We believe that these were first exhibited by M. Duboscq, of Paris, at a meeting of the British Association, some six years ago, at Glasgow. Since then, an immense variety of microscopic photographs have been produced; and they are now a common article of sale at the opticians, &c.

PHOTOGRAPHIC REGISTRATION.

Amongst the various uses to which photography has been applied, is that of registering magnetic, astronomical, barometrical, and other observations. As each of its applications is made in a form suitable to the instrument, the indications of which have to be noted, we shall confine our remarks to the explanation of the general plan, rather than to separate details.

A piece of paper rendered sensitive to the action of light by any of the processes mentioned in the previous pages, is fixed round a cylinder. This is moved by clock-work, so as to rotate once in twelve or twenty-four hours; and the paper is divided into parts, so that each hour or part of an hour is marked on its surface. The whole is excluded from light, except at a small aperture, through which the rays of a lamp, concentrated by means of a reflector, alone can pass. Now the light so admitted will at once act on the paper opposed thereto; and as the paper is continually revolving as the day passes on, any ray falling on the surface will produce a black mark at a place on the paper, indicating the time of day.

When the paper is removed, a long and irregular line will be observed on the surface; and the position of this line will thus indicate—say the vibration of a magnetic needle, the rise or fall of the mercury in the barometer tube, &c., according to the mechanical and other arrangements to which it has been adapted.

It will be at once seen that this plan is of the greatest possible value to the philosopher. Day or night, the registration can be carried on with the most extreme accuracy: no chance of error need creep in if proper precautions are taken; and the results, printed by the hand of nature, are permanent, and not like the efforts of the human mind, which are intermittent from the necessity of rest, or uncertain from their infirmity. The plan is extensively employed in most of the public and private observatories of our own and other countries

COLOURING PHOTOGRAPHS.

We regret to say, that all attempts to obtain pictures with natural colours, by means of photography, have, as yet, been unsuccessful. The photographic artist has, therefore, endeavoured to supply this want by applying colours to photographs, and so producing a picture resembling that produced by the painter.

The practice was first commenced with Daguerreotypes, which, from their heavy metallic hue, were anything but flattering likenesses in many cases. After the collodion process was introduced, the art of colouring was still more largely practised, and has now arrived, in many instances, to a high artistic rank; although, when in the hands of the majority of those who employ it, the results are scarcely better than hideous daubs, in which the value (if any) of the photograph is entirely concealed, and its defects strongly magnified.

The colours, in a state of impalpable powder, are applied by means of a camel-hair pencil, moistened with a little water. Some highly-finished oil portraits have been produced by leading photographers; which have the advantage of being exact likenesses, together with that peculiarly pleasing expression which the taste of a thorough artist can alone give.

---

* See *ante*, p. 68.

We have frequently employed photography for another purpose, to which we will refer; and our remarks may be useful to the managers of Mechanics' Institutions, &c. The ordinary mode of producing dissolving views, is that of first sketching on glass by means of Indian ink, and then of filling up the outlines with transparent colours. Instead of this plan, we have had portraits and landscapes first photographed, and afterwards coloured by the artist. The result is a pleasing and accurate picture, which, when magnified by means of the dissolving views or magic lantern, presents an exact illustration of an object on the screen. We have employed magnifying powers, varying from one to sixteen thousand times superficial, and can strongly recommend our plan to all who are desirous of having sets of views painted.

Care must be taken that the colours employed are quite transparent; that the collodion film is not too thick; and it is also essential that the lenses of the lanterns should be as free as possible from spherical aberration. The effects of this are avoided by the artist, as he paints all straight lines at a slight curvature: of course this is not allowed for in the photograph, which strictly represents objects as they actually appear.

PHOTOGRAPHY BY ARTIFICIAL LIGHT.

The comparative absence of the chemical or actinic rays in most kinds of artificial light, render them unsuitable for the purposes of photography in many cases. It is, however, possible to obtain pictures by means of the oxy-hydrogen light, the electric light, and the combustion of some substances; and as there has been but little published on the subject, we shall confine our remarks to our own researches and experiments.

We have succeeded in taking likenesses by means of the following arrangements:—

1. *The Electric Light.*—For this purpose a powerful voltaic battery of fifty cells of Grove's battery was employed, together with a modification of Duboscq's electric lamp. The cells were arranged in single series, and each platina exposed an active surface of twenty-eight square inches. The length of flame was about half an inch, and, as nearly as could be judged, about a quarter of an inch thick. No reflector was employed, and the sitter was placed at about three feet from the charcoal points. Ordinary collodionised plates, which, on an average, required from twenty to fifty seconds' exposure in the camera by daylight, were used; the manipulation, &c., being identical with the usual mode pursued in daylight photography.

An equally good photograph was produced by an exposure to the electric light for about thirty to forty seconds, so far as the intensity of the light and shade of a positive was concerned. But, strange to say, the same objection exists to such photographs as is found in the use of the electric light for illuminating purposes—namely, that of the excessive depth of light and shadows, all half tones seeming to be entirely lost.

To remedy this, we tried a variety of arrangements, but entirely without success. The face of the sitter presented a deadly or ghastly white appearance on the plate; whilst any shaded or dark part of the dress or skin, was equally black. The picture itself was therefore divided into two appearances only, and was entirely deficient of pleasing expression. In no trial with a varying strength of the light, did we succeed in tempering this excessive contrast of effect.

2. *The Oxy-hydrogen Light.*—Owing to a less amount of actinic rays in this light, the solarising effect is not so intense. Longer time of exposure is required, even to the extent of one minute; depending, of course, on the sensitive nature of the plate.

3. *The Combustion of Phosphorus in Oxygen.*—By this plan a most intense light is produced; but owing to its short continuance, it is of little or no avail. The pictures are, however, softer than those produced by the means already referred to, and have a more intimate blending of light and shade.

4. *Moule's Photogenic Arrangement.*—Unaware of Mr. Moule's invention, we tried, in 1856, some experiments with a compound called blue fire, composed of the following ingredients:—

Nitre	4 parts.
Sulphur	2 ,,
Sulphide of antimony	1 part.

And found that a portrait, nearly equal to that obtained by daylight, can be produced. Mr. Moule, we believe, adopts some chemical compound similar to that we have named; but in addition he uses a lamp, in which the substance is burned. Photographs taken by such means are very good, and well defined as regards half tones, &c. The process, however, has not been largely employed; and, so far as we know, has never been used commercially, having been confined chiefly to lecture-table purposes.

Ordinary gas, oil, and paraffine lights, have a very slight action on collodionised plates; and we shall therefore not enter into details respecting them.

The electric and oxy-hydrogen lights, but especially the former, are of great value in certain circumstances. In many of the museums of this and other countries, there are objects which, from their size, &c., are necessarily placed in positions where sufficient daylight can scarcely impinge on them for the purposes of the photographer. In such cases, the electric light has been frequently employed with great success; and photographs of many interesting objects have been obtained. As the objections which exist to portraits taken thus, are rather advantageous when the pictures of inanimate articles are required, the electric and oxy-hydrogen lights afford the most eligible means of illumination in such cases.

CELESTIAL PHOTOGRAPHY.

One of the most surprising achievements of modern science, is that of taking views of the heavenly bodies; which, in the case of the moon, are so accurate, as to permit our tracing the valleys and mountains represented on photographs of her surface. The difficulty incident to such attempts, will be better estimated when we compare the perfect stillness required of a person sitting for a likeness, with the circumstances which have to be allowed for in celestial photography. Some of these we may name, in connection with lunar photography. In the first place, the earth is rotating on its axis, at the rate of 1,000 miles per hour. At the same time, we are travelling through space at a rapid rate. The moon, again, is revolving round the earth at the rate of about 2,000 miles per hour. The difficulty, therefore, at once presents itself, as to how sufficient absence of motion, or its equivalent, can be obtained for a few seconds of time. This is managed by so arranging the telescope, &c., by means of clockwork, as that it shall travel an angular distance equal to that traversed by the heavenly body in any space of time.

Our readers will understand the principle of this, if we afford them a familiar illustration. We will suppose the case of a steam-boat in motion, towards which a telescope is being pointed by an observer on shore. The instrument, if gradually shifted, will apparently present the steamer to the eye at a state of rest; and the angular motion of the telescope will require to be less, exactly in proportion to the distance of the steam-boat.

Now the heavenly bodies are in a similar position; and as we know the exact rate of their, and our own, passage through space, it becomes a matter of pure mechanical arrangement to accommodate the angular motion of our instruments to them. This is done by means of clockwork; and the arrangements lately employed have afforded some very interesting results.

The most recent instances of this application of photography, is that effected during the solar eclipse of July 18th, 1860. To those of our readers who are unacquainted with astronomy, we may explain, that some peculiar appearances which are presented during an eclipse of the sun, have afforded matter of deep discussion on the part of astronomers. Of these, the beads, red flames, &c., which are frequently seen in an annular or total eclipse, are the most prominent. The intense excitement which naturally affects the coolest observer when phenomena of the deepest interest, and lasting but a few seconds of time, take place, is enough to unfit any one for taking accurate observations. Besides this, the power and peculiarities of vision of each person so engaged, vary to so great an extent, as to give an entirely different complexion to the observations taken. Photography here, therefore, steps in. The inanimate paper is subject to no emotion, or disturbing cause, and it affords a ready and efficient means of registering an observation, which cannot possibly be otherwise than accurate.

For the purpose of obtaining varied and positive results, some of the leading philosophers of our time betook themselves to various places over which the shadow of the moon would pass. They were abundantly provided with instruments for ordinary and photographic observation; and when possible, the duties of observing were divided amongst a number of persons, so that each might make one phenomenon his special duty to attend to. We must confine ourselves entirely to the photographic results; and are indebted for such to the *Photographic News* Almanac, from which the following extracts have been made:—

"M. Foucault studied the corona, both optically and photographically. Immediately after the disappearance of the last solar ray of direct light, a prepared plate was exposed ten seconds; then a second plate was exposed twenty seconds; and lastly, a third plate was exposed during sixty seconds: they were developed by sulphate of iron, and fixed with cyanide of potassium, with the object of obtaining direct positives. Owing to a vibration accidentally given to the apparatus, four images were impressed on the first sensitive plate, in a very short space of time; three at least in less than a quarter of a second each: these possessed a peculiar interest and value; they did not give a complete picture of the aureola, but only of a circumference of the circle surrounding the obscure disc of the moon. On the side where the interior contact took place, the circular contour presented greater intensity, which confirmed the impression entertained by M. Leverrier. Irregularities, similarly situated, on these three images were remarked, which appeared to be an exaggerated representation of the lunar contour. When the proofs were placed in the actual position of the planets, it was seen, that among the indentations, two were principal and contiguous, situated at the inferior and eastern extremity of a diameter inclined at forty-five degrees. The three other proofs gave an extension to the aureola, which increased with the duration of the exposure. The aureola diminished in proportion as it receded from the planet, and its line of demarcation became lost in the tint of the ground which represented the sky. In the proof exposed sixty seconds, the aureola extended sensibly to a distance equal to thrice the radius of the central disc. But, in certain particular directions, the aureola exhibited positive and negative variations in its intensity, producing the representation of a glory. One of them, better defined than the other, was prolonged, in all the proofs, beyond the rest of the aureola, and seemed to emanate exactly from the point occupied by the indentation on the edge of the moon, already described.

"Such are the results of an experiment undertaken solely to ascertain the photogenic activity of the aureola on wet collodion. The harmony prevailing among the six proofs, supply positive elements for the discussion of the nature of the aureola."

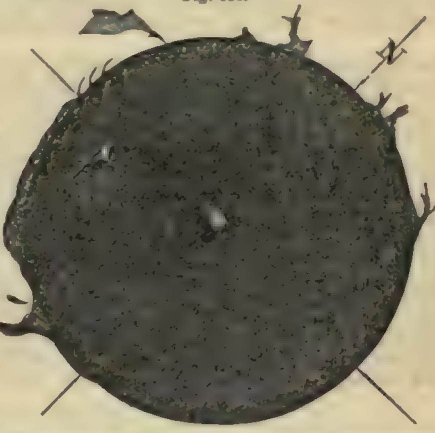
The Astronomer Royal, Dr. Airy, proceeded to Spain; and the following contains the substance of a paper read by him before the British Association, at the meeting held in Manchester, in September, 1861.

In the early part of his discourse, Dr. Airy gave a general account of the cause and phenomena of eclipses; entering into a great variety of astronomical data, which it would be foreign to our purpose to repeat. Having disposed of the general nature of eclipses, he called attention to some peculiar appearances, termed "Baily's Beads"—a number of bright spots, which have been noticed on the edge of the sun just before an eclipse became total. In 1842, red flames were noticed as protuberances from the edge of the sun; but the surprise and unprepared state of the spectators, unfitted them to make accurate observations or detailed reports. In 1850, during a solar eclipse, similar, and additional, phenomena were noticed; and due preparation having been made to observe the same in 1851, several philosophers, including Dr. Airy, proceeded to Sweden, and other places, for the purpose of making a fresh series of observations. A variety of interesting results were obtained; but still, the uncertainty of human power, and the mental excitement under which all the observers suffered, invalidated any conclusions at which they arrived, and still left much to be desired in the way of truthful result.

Accordingly, in 1860, a large party of astronomers, and others, proceeded from this country to Spain, well provided with apparatus of all kinds, and also with a complete set of instruments, by means of which the photographic art was put into full operation; and the entire proceedings were attended with the greatest success. Similar arrangements of clockwork, to which we have already alluded, were employed, and an accuracy of result was obtained which left scarce anything to be desired.

Amongst the most successful of the operations were those by Mr. De la Rue; which he conducted by means of apparatus he had fitted specially for the purpose. The annexed engraving represents a photograph of the eclipse at its totality, and the red flames issuing from the outer edge of the sun.

Fig. 160.



The photographs thus taken were subsequently compared with those effected by other operators, and their exact similarity was so great, as to prove the extreme value of photography in its application to astronomical observations. Indeed, many occurrences unperceived by the observer were thus registered, and additional light was thrown on a variety of previously obscure phenomena.

CONCLUDING REMARKS ON PHOTOGRAPHY.

In the preceding pages, we have endeavoured to present the reader with a *résumé* of most of the photographic processes in use at the present time, together with others which have been superseded by various experiments. In doing so, our desire has been to assist those who may be almost entirely ignorant of the minutiæ of scientific researches, and the difficulties which attend their pursuit. We have attempted first to introduce to the elements; and, subsequently, to expand to matters of great difficulty and importance in some branches of the art.

We must, however, remark, that the art of photography, perhaps, of all others, is continually undergoing rapid change and improvement; and if any of our readers have been so far interested in our experiments, &c., as to be induced to repeat them, we may state, that the various photographic periodicals may, at all times, be advantageously consulted; because, by them, the new processes, as they are made public, may be learned, and considerable saving of time and money effected.

Despite the elaborate treatises which have been published, the chemistry of photography is as yet but imperfectly understood. The varying character of the numerous recipes which we have given for solutions, baths, &c., proves that, to a great extent, empiricism, rather than strict scientific rule, is the order of the day. Indeed, if our readers had the patience and time to wade through the various processes which are continually being published, and would compare the directions given with such processes, for instance, as those of the electrotype, they would at once perceive the absence of exactness and precision which should always be sought after in the application of experimental philosophy. Many a discovery in the art has been made by an accidental mixture of chemicals; and frequently pure accident has been the best assistant to photographic progress. We may state, that photography stands now in a somewhat similar position to what alchymy does to chemistry; and it is almost certain, that all our successes hitherto will form but the introduction to others of a far more enlarged kind. This, however, is a matter of great importance and of encouragement to every attentive student, because an accident may just as readily lead him to new and valuable discoveries as it would the most practised hand. In mathematics a new discovery is almost impossible, so well has that branch of human knowledge been investigated; but in experimental science, we are continually stumbling over a novelty which often only requires elaboration to convert into a valuable addition to our stock of well-ascertained facts.

Addressing ourselves to our young readers, or to self-taught students, we would observe, that however often a process or experiment be repeated, something new may be detected if close and keen observation be employed. There are hundreds of class experiments that have been long well known to every scientific inquirer, which present new features on each repetition. Indeed, many of our most important discoveries have been made from occurrences which are familiar to every human being. The invention and perfection of the steam-engine, by James Watt, is a remarkable instance of the kind. Applying these remarks to photography, we may state, that no two collodionised plates ever present the same appearances; the effect of developing solutions equally varies; and so on. Now, as each of these variations has its own cause, and cannot be the result of accident—as such must take place according to some definite, although, perhaps, unknown law—we cannot but perceive that a failure always contains a germ of some future success; whilst success itself, like prosperity in life, often hides that which would become a great advantage.

We make these remarks with another object: it is that of urging on all, the duty of at once making public any fact of importance which they may meet with. This is easily done by communicating the particulars in a terse, pithy manner to any of the photographic societies or periodicals, each of which is at all times open to the reception of useful information. The discovery of a new principle or fact, does not constitute a right of property in its discoverer, however justly he may make its application a matter of profit. The laws of nature are the property of every man; but as the application of each requires special training and character of mind, it is only just that those who have such acquirements (and they are only to be obtained by great patience and perseverance) should reap a proper reward for their exercise. This spirit, we are happy to say, has been eminently observed throughout the history of photography, and is as creditable to its possessors as it has proved beneficial to society at large. By pursuing the course we are recommending, the experimenter, whilst assisting his co-workers, will put forward, by his generosity, a claim on them for reciprocal conduct, and the result will be a rapid advance in every branch of this interesting art.

Having thus investigated the laws of light, and their applications, we shall now direct attention to the phenomena presented by another of the undulatory forces—namely, that of Electricity. We shall find many analogies between it and heat and light; some of which we have already pointed out in our general introduction to physical science.* The subject on which we are about to enter, affords a vast variety of interesting and brilliant experiments, and will so far relieve the mind of the tyro by exciting simultaneously the eye and the mind. The science of light is necessarily of considerable difficulty, although of deep interest: it involves an intelligent and deep study, especially in connexion with mathematical science, of which it is a most important application. For the sake of simplifying the subject, we have avoided, as far as possible, all difficulties of the kind, and have therefore given results rather than extended details.

Electricity, on the other hand, is a purely experimental subject: many of its phenomena are familiar to every one; and we trust that our exposition of them will suffice to give the attentive reader a general knowledge and insight into its laws and applications.

* See *ante*, p. 1, *et seq.*

ADDENDA ON THE SPECTRUM ANALYSIS.

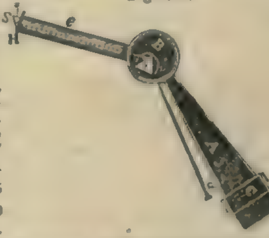
At the time our remarks on the new discoveries of Messrs. Bunsen and Kirchkoff were written,† the published information on the subject was very imperfect. We have, therefore, availed ourselves of a most interesting paper, read by Dr. Miller, at the meeting of the British Association in Manchester, in September, 1861; and are indebted for a *résumé* and engravings to the *London Review*, of Oct. 5th, in which a full report may be found.

The learned professor commenced by giving historical details of the various discoveries which had been made in connection with the subject, from the time of Newton to the present day; to which we have previously referred incidentally. Many facts bearing on the question have already been mentioned in the previous pages; we shall, therefore, confine our extracts to the practical details and results obtained by recent experimenters on the Photographic Spectra of the Electric Light, in contrast with those of the solar rays.

† See *ante*, p. 55.

ON THE PHOTOGRAPHIC SPECTRA OF THE ELECTRIC LIGHT.

Fig. 161.



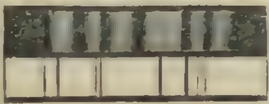
Apparatus for Photographing Spectra.

"A plan of the apparatus by which the spectra may be photographed is shown in the figure (Fig. 161). It consists of an ordinary camera-obscura, C, attached to the end of a long wooden tube, A, which opens into a long cylindrical box, B, within which is a prism of heavy flint glass, or of bisulphide of carbon, *i*. At *l* is a lens of 15 inches focal length, and at *s* is a slit parallel to the axis of the prism. The slit is adjusted so that it shall be distant from the lens 30 inches or twice its focal length, and the screen of the camera is at an equal distance from the lens. The prism can be turned round its own axis by the lever, *d*, and the tube, A, can be adjusted so as to vary the angle with the brass tube, *e*; a small reflecting prism is, when necessary, placed so as to cover half the slit, *s*, and to reflect light from a second source so as to form a second spectrum on the plate, as in Steinheil's apparatus.

"If the prism be so adjusted as to throw the solar rays reflected from a heliostat upon the screen of the camera, the wires which transmit the sparks from a Rhumkorff's coil are placed in front of the uncovered portion of the slit, and the two spectra are simultaneously impressed. The solar beam is easily intercepted at the proper time by means of a small screen, and the electric spectrum is allowed to continue its action for two, three, or six minutes, as may be necessary.

"Although with each of the metals—including platina, gold, silver, copper, iron, bismuth, cadmium, zinc, aluminum, magnesium—when the spark was taken in air, decided photographs were obtained, it appeared that in each case the impressed spectrum was very nearly the same, proving that the lines produced were not those which were characteristic of the metal, but that they were the lines due to the incandescence of the air. These bright lines, it is important to observe, do not correspond to any black lines in the solar spectrum, apparently indicating the absence of nitrogen in the solar atmosphere.

Fig. 162.



Platina and Solar Spectra.

"The peculiar lines of the metal seem to be chiefly confined to the *visible* portion of the spectrum, and these have little or no photographic power.

"*Metallic Spectra, showing Corresponding Bands.*

Fig. 163.—Gold Spectrum.

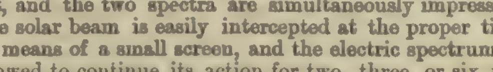


Fig. 164.—Silver Spectrum.

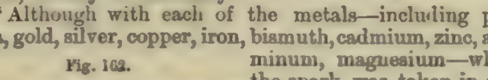

Fig. 165.—Copper and Solar Spectra.†

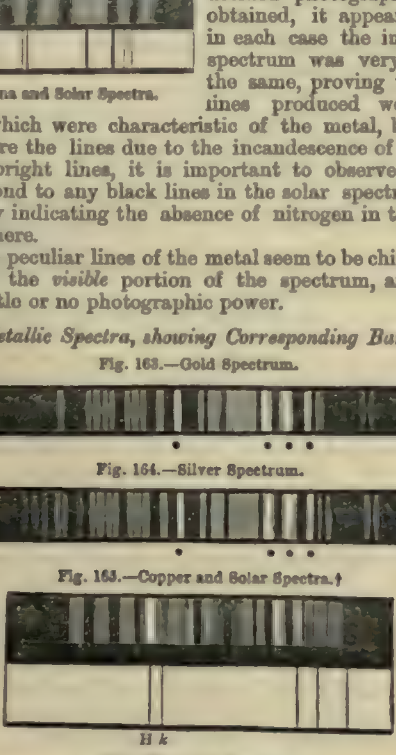

Fig. 166.—Iron Spectrum.

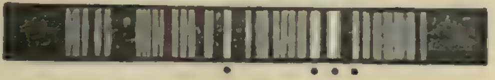

Fig. 167.—Zinc Spectrum.

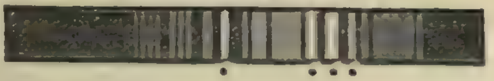
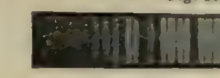


"This was singularly exemplified by repeating the experiments upon the same metal in air, and in a continuous current of pure hydrogen. In these experiments two iron or platina wires were sealed into a bulb blown upon a long narrow tube which conveyed the gas under trial. Under these circumstances, for example, iron gave in hydrogen a spectrum in which a bright orange and a strong green band were visible, besides a few faint lines in the blue. Although the light produced by the action of the coil was allowed to fall for ten minutes upon a sensitive collodion surface, scarcely a trace of any action was perceived (Fig. 168); whilst in five minutes in the air, a powerful impression with numerous bands was obtained (Fig. 166).

Fig. 168.



Iron Spectrum in Hydrogen.

"Similar results were obtained with platina (Figs. 169 and 162). When carbonic acid was substituted for hydrogen, maintaining a continuous current of the pure gas during the whole experiment, the effect upon the sensitive plate was scarcely more marked.

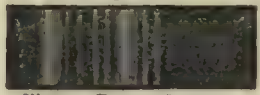
Fig. 169.

Platina Spectrum in Hydrogen.

"No photographic impression was obtained in ten minutes of the brilliant red line produced by sending the discharge of Rhumkorff's coil through one of Geissler's hydrogen vacua.

"Fig. 170 shows a copy of the photographic spectrum produced by the violet line of light obtained from one of Geissler's nitrogen vacua. The lines produced by the different metals which are characteristic of them, are best displayed by using, as Wheatstone did originally, somewhat feeble electrical discharges. When, for instance, the Leyden jar is introduced into the secondary current of the Rhumkorff's coil, as practised by Grove, the light is principally produced, as Alter and Angström have shown, by the ignition of the atmospheric air, and particularly by the nitrogen. The spectrum will appear to be filled with brilliant lines, which are nearly the same, whatever electrodes are used; but if the Leyden jar be removed, the characteristic bands of the metals may be distinctly seen. Those of iron are only well seen when the metal is red-hot, but not actually burning.

Fig. 170.



Nitrogen Vacuum Spectrum.

"Most of the metals give, as was remarked by Masson, a feeble continuous spectrum streaked by bright bands of varying intensity; and this sombre ground is not due to the ignition of the electrodes, as may be at once seen by the instant change presented in the appearance of the spectrum, if one of the electrodes does become incandescent.

"It was early remarked by Mr. Talbot, that, in the spectra of coloured flames, the nature of the acid did not influence the position of the bright lines of the spectrum, which he found was dependent upon the metal employed; and this remark has been confirmed by all subsequent observers.

"But the case is very different in the absorption bands produced by the vapours of coloured bodies. There the nature of both constituents of the compound is essentially connected with the production of absorption bands. Chlorine combined with hydrogen gives no bands by absorption in any moderate thickness.

"Chlorous acid and peroxide of chlorine both produce the same set of bands; while hypochlorous acid, although a strongly coloured vapour, and containing the same elements, oxygen and chlorine, produces no absorption bands. Again, the brownish-red vapours of perchloride of iron produce no absorption bands; but iron, when converted into vapour in a flame, gives out bands which are independent of the form in which it occurs combined.

"These anomalies appear, however, to admit of an easy explanation, if we suppose that in every case the compound is decomposed in the flame, either simply by the high temperature, just as Grove has shown that water is. In other cases of the production of bright lines by the introduction of a metallic salt into the flame of burning bodies, the reducing influence of the hydrogen, and other combustible constituents of the burning body, would decompose the salt, liberating the metal, which, after producing its characteristic lines, would immediately become oxidised, and be carried off in the ascending current. In the voltaic arc this decomposition must of necessity take place by electrolytic action.

"The compound gases, protoxide and deutoxide of nitrogen, give, when electrified, the same series of bright bands as Plücker has shown, which their constituents when uncombined furnish. Aqueous vapour always gives the bright lines due to hydrogen, and hydrochloric acid the mixed system of lines which would be produced by incandescent hydrogen and chlorine.

---

† Focus rather shorter than that of other photographs.

"There is obviously a marked difference between the effect of intense ignition upon most of the metallic and non-metallic bodies.

"The observations of Plücker upon the spectra of iodine, bromine, and chlorine, show that they give, when ignited, a very different series of bands to those which they furnish by absorption, as Dr. Gladstone has already pointed out; but it is interesting to remark, that in the case of hydrogen, which, chemically, is so like a metal, we have a comparatively simple spectrum, in which the three principal bright lines correspond to Fraunhofer's dark lines, C, F, and G (Plücker). It is, however, to be specially noted, that hydrogen occasions no perceptible absorption bands at ordinary temperatures in such thicknesses as we can command in our experiments; and the vapour of boiling mercury is also destitute of any absorptive action, although mercury, when ignited by the electric spark, gives a characteristic and brilliant series.

"The following experiment suggested itself to the author as a direct test of Kirchkoff's theory:—Two gas-burners, into which were introduced chloride of sodium on the wick of a spirit-lamp, were placed so as to illuminate equally the opposite sides of a sheet of paper partially greased; the rays of the electric light, screened from the photometric surface, suitably protected, were made to traverse one of the flames. If the yellow rays of the light were absorbed by the sodium flame, the light emitted laterally by the flame should be sensibly increased. The experiment, however, failed to indicate any such increase in the brilliancy of the flame, possibly because the eye is not sufficiently sensitive to detect the slight difference which was to be expected."

From a perusal of the interesting facts contained in the preceding remarks and experiments, our readers will perceive that every solid body, when brought into a state of vapour and incandescence, produces definite and decided effects in reference to the bands of the spectrum. Each body, in fact, has a spectrum of its own; the perfection and constant identity of which is preserved, provided no other interfering cause be present. Great precautions, however, are required in performing the experiments, especially by those persons who may not be accustomed to delicate investigations. Even solid but invisible bodies floating in the atmosphere may invalidate the result; and, under certain circumstances, the minute portion of common salt often present in the air, has produced a spectrum, of the sodium kind, much to the perplexity of the observer. It must be borne in mind that the new method of analysis is so excessively refined and exact, that every possible precaution may fail in affording results which might be expected; and substances in proportions so small as to defy all other means for their detection, may intrude themselves, and so modify the spectral appearances.

The spectrum analysis has been extensively investigated and employed by many eminent observers; and its indications have been used in numerous branches of research in various departments of optical science. All luminous bodies may be examined by it; and if the results are compared with certain standards previously obtained, inferences may be drawn with respect to the colour of light and its cause, which would be utterly unattainable by any other means. For instance, much dispute respecting the nature of the solar rays and atmosphere has been prevalent, and numerous theories have been advanced to account for the production of both the heat and light of the sun. By means of the spectrum analysis, however, Professor Airy, the Astronomer Royal, does not hesitate to affirm that the surface of the sun is in a state of strong incandescence; that immense bodies of vapour are constantly arising therefrom; and even the spectrum produced by iron in the state of vapour has been distinctly noticed in the solar light.

In a similar manner, the light of the planets, fixed stars, comets, &c, is readily examined, and compared with that of the solar rays. A new means of investigation is thus put into the hands of the philosopher. The astronomer, the mathematician, and the chemist, are thus jointly called in to determine some of the most interesting problems of astronomy. The theories and facts of each branch of science are thus correlated; the deductions of each are checked or modified by each other; and both the chances and sources of error are diminished in a wonderful and satisfactory manner.

To those of our readers who may be desirous of repeating the experiments, we may mention, that complete apparatus for the purpose is now made by the leading philosophical instrument-makers in London, in which all the requisite minutiæ of construction, &c., are fully attended to. This method of analysis is, therefore, within reach of any one possessing a tolerable acquaintance with optical and chemical science; and will doubtless prove a source of extensive discovery in physical science generally.

Like all new inventions, its use may at first lead to crude and indigested theories. In the hands of many observers, however, that evil will meet with its own correction; and as soon as a sufficient number of facts has been collected, we shall be able to make safe deductions. It is more than likely that the spectrum analysis will prove, in a physical point of view, as beneficial and useful an adjunct as did the invention of fluxions, or the differential calculus in the mathematical department of astronomy and allied sciences.

SECTION III.

ELECTRICITY, AND ITS APPLICATIONS.

CHAPTER I.

FRICTIONAL ELECTRICITY.

Having already considered separately the forces of Heat and Light, we shall now undertake the investigation of phenomena connected with that of Electricity.

As a branch of experimental science, electricity is of comparatively modern date. It is true that the ancients were acquainted with what we should now term elementary facts. Thus, Thales was aware that certain resinous substances, especially amber, would, on being sharply rubbed, attract light bodies to its surface. It was not, however, till within the last century, that such, and similar results, were philosophically investigated, and the foundation of electrical science was properly laid.

We shall not expend any space in a separate historical sketch of our subject; such will naturally fall into our pages as we describe various apparatus which have been invented with the object of illustrating the electrical phenomena. The unpleasant office will thus be avoided, of deciding the relative claims which have been advanced on the part of individuals, as to their just rights to the merits of discoveries they have made; which are at all times liable to be unsatisfactorily dealt with, and to call up the criticisms of a host of partisans.

The term "electricity" has been derived from the Greek word "electron," which signifies amber; and as such, the science and its name are associated with the early experiments of Thales, the Milesian philosopher.

We have endeavoured to familiarise the minds of our readers with the doctrines of latent forces in our two previous sections.* Electricity, like light and heat, is obedient to the same law; and, so far as our experience goes, there is no body with which we are acquainted, which cannot afford us, if proper means are employed, some evidence of the existence of electricity.

There are, however, chiefly two sources which we can employ for the purpose of disturbing the electrical equilibrium; or, in other words, of educing electric forces: these are motion, or mechanical action, which is chiefly employed under the form of friction; and chemical action, when it takes place in the union or division of two or more bodies. There is, however, another source—namely, that of magnetism, which, by a peculiar arrangement, affords us what has been frequently termed the electric fluid.

It is proper that we should here explain some terms which are continually employed by writers on electricity. These are, "current," "fluid," &c.; and which had their origin in the speculations of early experimenters. Even in the *parlance* of daily life these terms are often employed; and thus it is frequently stated, "that the electric fluid" struck a building.

These terms, and expressions involving them, have great convenience in conveying the idea of a passing or moving force. Hence, strictly philosophical definitions often contain such remarks as, that "the electric current" passes in a certain direction. Now, our modern views classify electricity with the undulatory forces; and we equally believe in the idea of electric, as in that of calorific and luminous undulations. If, therefore, in the following pages, we employ the terms to which we have referred, our readers must understand that we do so with the limitations we have mentioned, and that we simply consult the convenience of expression rather than peculiar exactness of speech.

Having thus guarded our future progress against any charge of looseness of expression, we shall now proceed to examine generally the various means by which the electric force is excited, the machines which are employed to illustrate its effects, and the laws which have been found as governing the occurrence of electrical effects. In doing this, we shall afford a vast variety of experiments, each of which may be readily tried by the student; and shall also put him in possession of means by which he may pursue his investigations at a comparatively moderate cost. We must defer the consideration of electricity, as produced by magnetic action, to a separate section, and confine our attention in this to the subjects of—

1. Frictional Electricity.
2. Voltaic Electricity.

Frictional Electricity.—When the particles of any body are disturbed from their quiet, and put in motion, there always results the production of heat, light, or electricity. They seem associated with matter in all its varied forms; and thus we find them in every state or condition of all bodies surrounding us.

The most ready means of evolving these forces is that of friction, of which daily life affords us numerous instances. The simple experiment of striking a lucifer-match will produce heat and light; and by means of a piece of apparatus, which we shall describe as we proceed, the evolution of electricity is also detected.

Former writers on electricity divided bodies into two classes—namely, electrics, and non-electrics. In the former, glass, resins, fur, silk, &c., were included; whilst the metals, because they did not seem to evolve electricity by friction, were termed non-electrics. At the present time, however, metals are the chief sources whence we obtain the force, the rationale of which we shall explain under the head of Voltaic Electricity.

The following experiments will illustrate the production of electricity by friction, and also exhibit some of the phenomena which attend its presence in a free state.

Experiment 1.—Dry a glass tube about eighteen inches long and an inch in diameter, by means of a cloth, warming it occasionally before a fire. Having also dried an old silk handkerchief, rub it briskly on the tube, and then hold the latter near to some feathers or small pieces of paper. These will be attracted to the tube, on which they will adhere for some time; they will, however, fly from it, returning to the table, again to fly to the tube. This motion they will continue until the electrical state of the tube is restored to the same condition as that of surrounding bodies, when the effect will cease.

Experiment 2.—Repeat the same experiment, but employ a roll of sealing-wax or of sulphur, a piece of amber, and a sheet of gutta-percha. The same effects will be produced.

---

* See *ante*, pp. 13 and 41.

Experiment 3.—Dry a sheet of paper before a fire until all moisture is removed from it, and then place it flat on a wooden table. Rub it briskly by means of a piece of India-rubber, and then suddenly lift it from the table surface. It will adhere thereto; but on being removed, and held vertically by the hand, it will approach to the fingers, if they are held near to it; and if the experiment be tried in a dark room, a small spark will be seen to pass when the fingers and the paper are nearly in contact. This experiment shows both an instance of *electrical attraction* and the production of the *electric spark*.

Experiment 4.—The fur of animals is also capable of affording considerable electrical effects. A piece of prepared skin may be rubbed, on the fur side, by means of a dry silk handkerchief. But the best plan is to rub the fur of a black cat, from the head towards the tail, either by means of the dry hand, or by a silk handkerchief. It will be found that each hair separates from its neighbour—giving an illustration of what is called *electrical repulsion*. And if the experiment be tried in a dark place, abundant sparks may be obtained by presenting the fingers to the fur; a sharp crackling sound being noticed at the same time.

The above will afford a sufficient variety of illustrations, showing how friction disturbs the natural electrical state of bodies; and an elementary idea will also be gained of what is meant by the terms "attraction" and "repulsion," in connexion with electricity; on which we shall treat more fully hereafter, as our subject expands to our view.

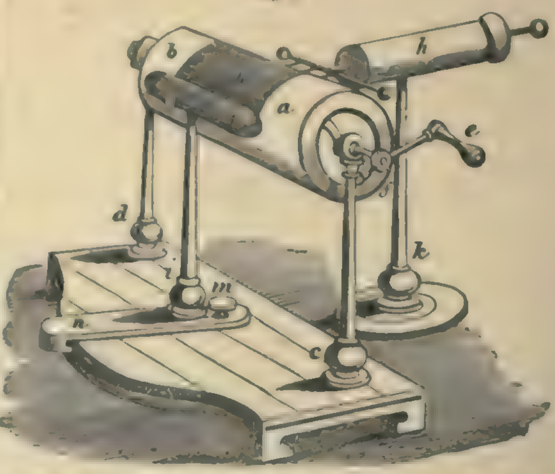
ELECTRICAL MACHINES.

We now proceed to describe a variety of arrangements, by means of which we obtain a considerable amount of free electricity. We consider this as the best course, because the student must be provided with some instrument of the kind before he can perform any experiments elucidating the law of the science. We shall describe those in ordinary use, and afterwards suggest simpler and cheaper arrangements, which any person, with an ordinary mechanical turn of mind, may, at a slight cost, construct for his own use.

Glass is universally employed in the usual form of electrical machines; and these are of two classes—the cylindrical and the plate. Each kind of machine has its advocate; but for all practical purposes, we recommend the use of the plate machine.

The cylindrical machine consists of a glass cylinder, mounted on two upright supports. On one side a rubber, which, by its friction, produces electricity, is supported on a glass rod, so as to press firmly on the surface of the glass. On the opposite side of the cylinder, a ball or cylinder of brass is placed; its surface, next to the cylinder, being coated with metal points. This is called the conductor, and, like the rubber, is also mounted on glass legs. We may here, without entering at present into the laws of conduction, observe, that glass, resin, gutta-percha, &c., convey electricity very slowly over their surface; and hence have been termed non-conductors. Now, as it is requisite that the force produced by the machine should be guided in one particular direction, the "conductor" itself is formed of a good conducting substance, which is always a metal; whilst it and the rubber are insulated electrically by means of the glass rods on which they stand. At the end of the conductor a brass knob is placed, from which the spark is received. Points being useful in collecting electricity, are, therefore, as we have stated, exposed to the excited glass surface; whilst the brass knob, which has a kind of conserving power, forms the terminal of the conductor at that point furthest from the machine. The cylinder is turned, by means of a handle, in the direction of from the rubber towards the conductor. The following engraving illustrates the various parts of a cylindrical machine.

Fig. 1.

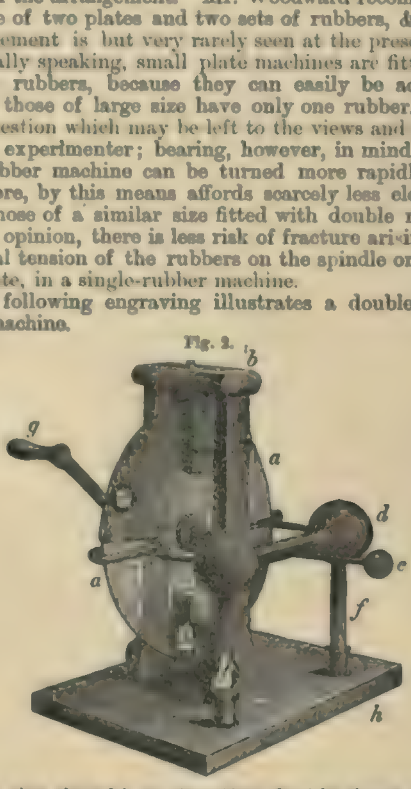


In the above diagram, *a b* represent the glass cylinder; *c d*, the legs by which it is supported; *e f*, the winch handle, by which the cylinder is turned; *g*, the rubber; *h*, the conductor; *i*, the glass support to the rubber; *k*, the glass support to the conductor; *m n*, a movable foot, by which the distance between the rubber and the cylinder can be adjusted.—These arrangements vary slightly, according to the views of the maker; but the different parts are common to every form of the machine.

As each kind of glass machine is similarly prepared for experimental purposes, we shall defer entering into such particulars till after the description of the plate machine. These have been made in various forms. Occasionally two rubbers are used, which are placed at the top and bottom of the plate. In another form, the rubber is placed on one side, and the conductor on the opposite side, of the arrangement. Mr. Woodward recommended the use of two plates and two sets of rubbers, &c.: this arrangement is but very rarely seen at the present day. Generally speaking, small plate machines are fitted with double rubbers, because they can easily be adjusted; whilst those of large size have only one rubber. This is a question which may be left to the views and decision of the experimenter; bearing, however, in mind, that a one-rubber machine can be turned more rapidly, and, therefore, by this means affords scarcely less electricity than those of a similar size fitted with double rubbers. In our opinion, there is less risk of fracture arising from unequal tension of the rubbers on the spindle or axis of the plate, in a single-rubber machine.

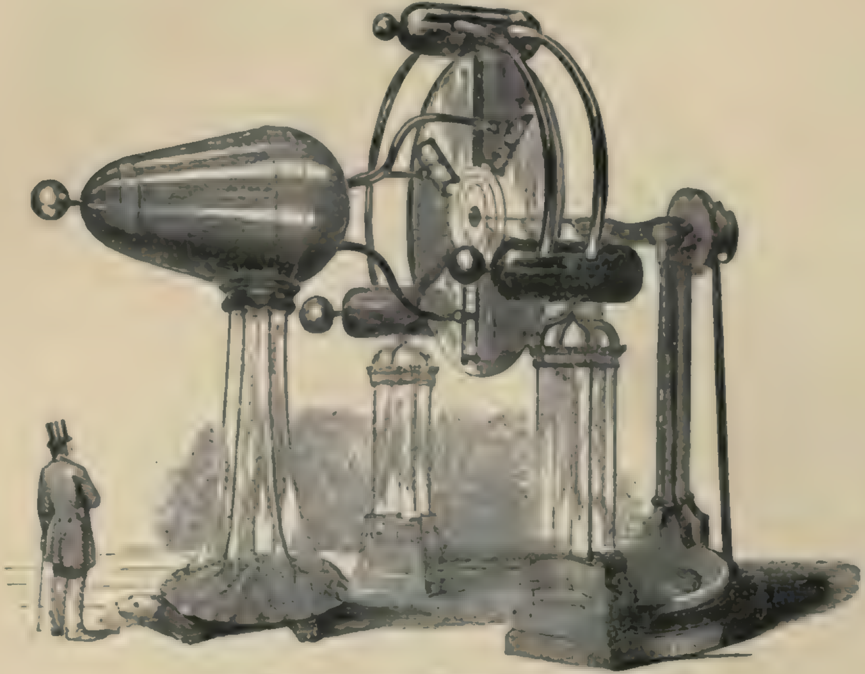
The following engraving illustrates a double-rubber plate machine.

Fig. 2.

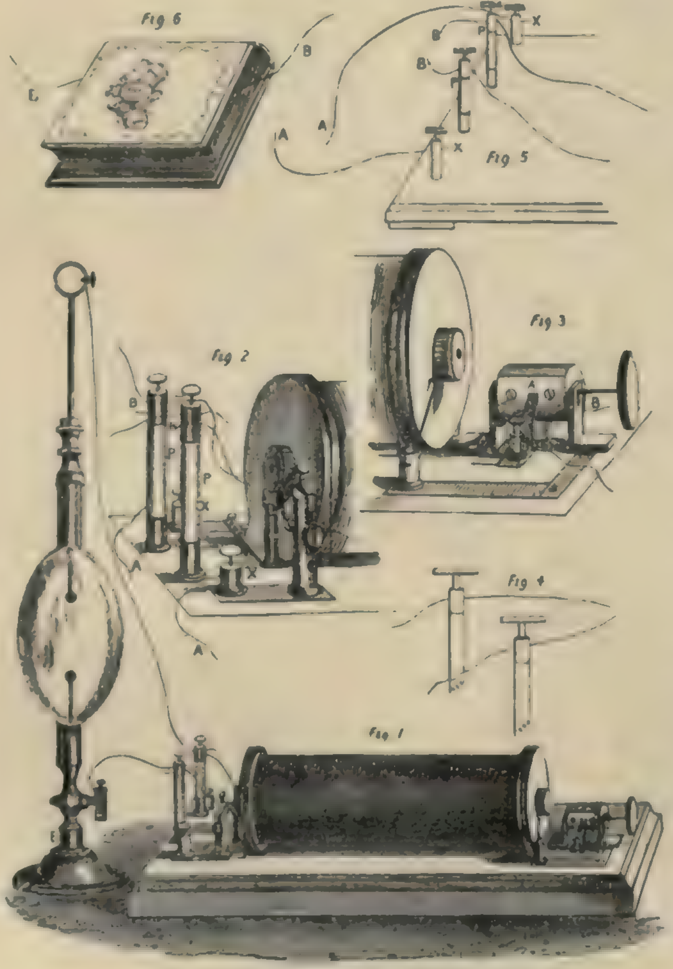


a a is the glass plate; *b b*, are the rubbers, fitted by clamps to an upright frame; *c* is a flap of black silk, which covers the glass plate; *d* is the conductor, which extends, by means of two arms covered with points, to the two sides of the plate: they terminate at the ends of the silk flaps, and so collect the electricity from the excited glass surface; *e* is the brass knob of the conductor; *f f*, are its two glass insulating supports; *g* is the handle, by means of which the plate is turned between the rubbers; *h* is the wooden table, on which the different parts of the machine are fixed.

ELECTRICITY AND ELECTRO-MAGNETISM.—PLATE I.



Ten-feet Glass Plate Electrical Machine. (See pages 171 and 242).



The Rhumkorf-coil Apparatus. (See pages 255—257).

An extended description of the Rhumkorf coil has been given at pages 255—257; but as its arrangement and management require great care, we have added, in the annexed cuts, an illustration of various minutiæ of detail, which will require the attention of the experimenter. It will be seen, that in Fig. 1, an ordinary exhausted receiver, such as is employed in Frictional Electricity, is represented as attached to the secondary wire of the coil; and the phenomena thus obtained, are extremely beautiful, if a good vacuum be produced by means of the air-pump.

Fig. 1. Rhumkorf's coil—E, exhausted receiver. (See Experiment 16, page 256).

Fig. 2. B, B, the poles of the fine coil; P, P, the glass pillars supporting them; A, A, wires from the battery, connecting it, by X, X, with the primary coil. (See also Fig. 5).

Fig. 3. A, the contact-breaker; B, its handle.

Fig. 4. The terminal wires of the secondary coil, arranged for the spark. (See Experiments 12—14, page 255).

Fig. 5. Outline view of Fig. 2.

Fig. 6. Book arranged for piercing the leaves, by spark from the secondary coil (See Experiment 17, page 256).

In a modification of the plate machine invented by Mr. Winter, an arm, extending to a height of three feet above the conductor, is placed, which, by its inductive effect, has the power of increasing the length and intensity of the spark to an astonishing degree.

Plate machines are made of various sizes. Indeed, we have experimented with them from those of one foot to one of seven feet diameter, of glass surface. The latter instrument may be seen at the Royal Polytechnic, Regent-street, London; and from it we have obtained sparks from six inches to two feet in length, depending on the dryness of the atmosphere and other circumstances, to which we shall have to allude. One of still larger size was daily used at the Panopticon, Leicester-square, some years ago. It had a plate ten feet in diameter, and was furnished with double rubbers and conductors. It is now in private hands, and is the finest specimen of a plate electrical machine yet produced.

We may here give a caution to those intending to purchase an instrument of this kind. The quality of glass used very materially affects the results which can be obtained. On one occasion, a twelve-inch plate which we possessed was cracked by being over-heated. On fitting the machine with a new plate, we found that we could not obtain anything like so good a spark as from that previously used. This was owing to a peculiar "greasiness" on the new glass. Some plates will attract moisture more than others; which, of all things, is most to be avoided in electrical experiments. The only general rule we can give is, that the more highly polished the glass, the fitter it is for the purposes of the electrician. Plates having specks, streaks, or spots on their surfaces, should be rejected; and the rim of the glass should have as complete a polish as the flat surface. It is, also, of the utmost importance, that the spindle which holds the plate, and on which it turns, should be fixed exactly in the centre. If this be not attended to, there will be an unequal pressure on the glass as it revolves, and risk of fracture will be inevitable.

Attention should also be paid to the construction of the clamp holding the rubbers, and to the mode in which the conductor is fixed on its supports, especially if placed on one glass rod only, as is frequently the case.

Before proceeding to the description of other forms of electrical machines, we will give directions for the management of those we have illustrated and explained; and we must impress on the mind of our readers, the necessity of a strict adherence to the precautions, &c., we shall mention, if they would obtain successful results in their electrical studies.

Some old silk handkerchiefs should be provided, which are much to be preferred to any other material, because silk does not afford fine fibres, as do cotton and linen. A few such fibres, if they get on the glass surface, adhere to it with great pertinacity, and have an astonishing effect in dispersing electricity.

The cylinder or plate machines are prepared for use as follows:—

1. Wipe the whole machine, glass, legs, handle, and foot, by means of a warm, dry handkerchief, so as to remove all dust or dirt which may have accumulated on its surface

2. Wash the cylinder or plate by means of a rag moistened with spirits of wine—having first loosened or removed the rubbers. This will cleanse away all hard matter which may have remained from previous experiments. The cylinder or plate is then to be rubbed with a dry handkerchief, until it has a high polish, and is quite free from every extraneous substance.

3. The rubbers should be carefully cleaned, if they have been previously in use, especially if any hard amalgam has been left on their surface. The more evenly they press on the glass, the greater will be the amount of electricity which will be produced.

After thus cleansing them, they may be slightly smeared with good tallow, and the amalgam is then to be spread evenly over the surface by means of a palette-knife. The amalgam is made by pounding together in a mortar—one ounce of zinc shavings, with two ounces of clean mercury. The two metals will soon combine; and the amalgam should be kept in a box or bottle, out of the air, because it would soon otherwise become oxidised and spoilt.

4. The rubbers having been thus amalgamated, are to be replaced and screwed up, so as to press evenly and firmly on the surface of the cylinder or plate; the silk flap being thrown back, lest it should become soiled. The handle of the machine is now to be turned gently, and the grease, &c., must be wiped off the machine until the rubbers no longer soil the surface. The silk flaps may now be placed over the glass, and the machine is ready for use.

5. As, however, all glass and metal surfaces receive a coating of moisture on being used in a room of higher temperature than their own, it is advisable to warm the whole machine before a fire, until its temperature exceeds that of the surrounding atmosphere. By this, all chance of the deposition of moisture is prevented. A silk handkerchief should be thrown over the machine whilst it is being warmed, so as to keep off any dust which might lodge on it.

6. As dryness and cleanliness are absolutely essential for success, the legs, and all other parts of the machine, should be continually wiped with warm, dry handkerchiefs, during the interval between the experiments.

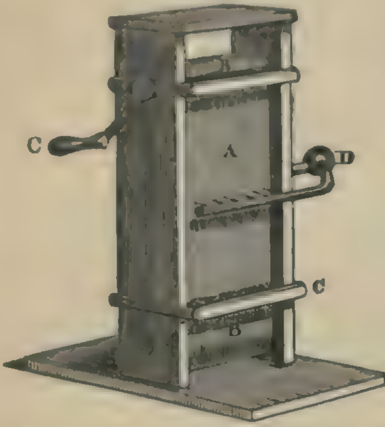
7. The rubbers of either machine should be connected, by means of a copper wire, with a gas or water-pipe; or, in the absence of these, the end of the wire should be allowed to rest on the floor, so as to keep up a continual production of electricity. In many works, brass chains are recommended; we, however, strongly urge the use of wire, which, being continuous, produces a far better effect than any chain.

A close observance of the above cautions, &c., will generally ensure successful experiments; but much depends on the state of the weather; for we have seen the spark of powerful machines, in the best order, reduced to one-fourth its usual length when a change has occurred from an east to a south-west wind. A simple indication of the state of the atmosphere, as suitable or otherwise for electrical experiments, is to be found by the fur on the back of the cat. If this produces a decided repulsion between the hairs on being rubbed, the electrician may expect success in his attempts with the machine; but sometimes the air is so loaded with moisture as to render it next to impossible to exhibit any effective results. We have seen more than one eminent lecturer risk his reputation with his audience by attempting electrical experiments in a crowded room. Of course, from ignorance of the cause of failure, the *vox populi* votes that the experimenter has neglected taking proper precautions. Whilst such may be partly true, our readers will soon become convinced, by experience, that every allowance should be made, under such circumstances, for "the pursuit of science under difficulties."

We may now proceed to describe machines constructed of resinous materials, which may easily be put together by any of our readers, and in which gutta-percha forms a chief material. Mr. Simmonds, of the west of England, has exhibited a machine composed of gutta-percha and resin, in the proportion of two of the former to one of the latter substances. In this, the plate (for it was a complete copy of the plate machine), the rubbers, handle, foot supports, and conductor, were all made of the same material; the points of the conductor were pins; and it was covered with tinfoil, to make it a good conducting surface. The rubbers were covered with rabbit-skin, and required no amalgam. A machine of this kind, which he favoured us with some six years ago, could be worked in any weather, provided it was first carefully wiped from dust. It seemed to have a very slight attraction for moisture; and, although the plate was no more than twelve inches in diameter, we have given a shock to twenty persons by means of a Leyden jar, under circumstances in which no glass plate machine could be made to work. If the plate machine, illustrated in Fig. 2, be taken as a pattern, and the material of which we gave the recipe, be used, any person may, at a trifling expense, put themselves in possession of one of these ingenious electrical contrivances.

Another form of gutta-percha machine was invented some years ago, and was, we believe, exhibited at the Exhibition in Hyde-park, in 1851. It consists of an endless band of gutta-percha, running over two rollers. The rubbers are formed of hard hair-brushes; and its general construction is illustrated in the following figure.

Fig. 3.



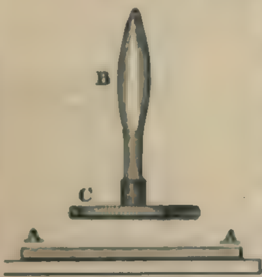
A represents the band of gutta-percha; B B are the two rubbers; C is the handle which turns the upper roller; the under one moving by the friction of the gutta-percha against its surface; D is the conductor, which extends in two arms, ended with points facing the gutta-percha band.

As we have never tried this form of machine, we can give no particulars with respect to its value. It, however, has the advantages of ready construction, slight cost, and, of course, does not require amalgamation or extended preparation before use, beyond that of cleaning all the surfaces from dust and dirt.

Perhaps the simplest form of electrical machine is that of the electrophorus, which, at a most trifling expenditure of trouble and expense, presents an opportunity for any one to try a vast number of electrical experiments. It may be constructed as follows:—

Into a tray of sheet-tin or zinc, half an inch deep, and twelve inches in diameter, pour melted yellow resin till the liquid reaches the top. This forms the sole of the electrophorus. A circular piece of zinc plate, nine inches in diameter, should have fixed to its centre a gutta-percha handle nine inches long. The plate should be quite level, and its edges smooth. The arrangement is represented in the annexed figure.

Fig. 4.



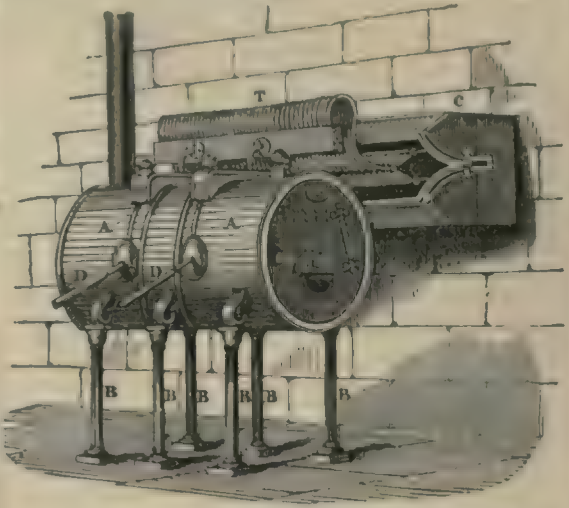
A represents the resin sole; B the gutta-percha handle; C the zinc plate.

The mode of exciting the electrophorus is very simple. The resin is, of course, allowed to cool, and it may then be rubbed briskly, by means of warm, dry flannel. The metal plate, held by the handle, is then placed on the resin plate. The *top* of the zinc is then to be touched by the finger, and it is then to be raised a few inches. On presenting the knuckle, a spark will pass to it. This process may be repeated for a long time, as the plate only requires occasional rubbing by means of the flannel. A continual supply of electricity may thus be obtained; the only inconvenience which is experienced, is that of continually lifting the zinc plate to obtain the spark.

We recommend our readers, especially the younger portion of them, to make one of these useful little instruments, as, in the absence of those of larger size, a great number of the experiments we shall mention in our future pages may be tried.

Another, and singular source of electricity, is that from the friction of pure water; which is effected by means of steam as it condenses at its exit from the boiler. Machines constructed for this purpose are called hydro-electric machines. The largest of the kind is that at the Polytechnic Institution, Regent-street; and as we there had it in daily use for several months together, we shall be somewhat particular in describing its construction, and the effects which may be obtained from it. The following engraving illustrates the external appearance of this instrument.

Fig. 5.



A A represents the boiler, which is about eight feet long, including the smoke-box. B B are six glass legs, which support and insulate the boiler. C is a box fitted with iron spikes or points. This box can be removed nearer or further from the boiler, and, by its proximity thereto, influences the length and intensity of the spark. D D are the handles, by means of which the steam is permitted to pass into, or to be shut from, a series of bent tubes, which are curved into the form of the letter S, and are represented at E E. These tubes are terminated by circular knobs, which enclose jets of partridge-wood, shaped of a cylindrical form, and having a jet somewhat resembling a bat's-wing gas-burner. As the steam passes from the boiler through the series of bent tubes to which we have alluded, it is partially condensed, and arrives at the jets in the state of minute particles of water. The pressure of the steam drives them with great force against the side of the jet, and thus the sides of the jet take the place of the rubber in this machine, and the pure water that of the glass. The action of the hydro-electric is therefore analogous to that of the glass machine in most respects. It has been stated, that the water used in the boiler should be almost, if not entirely, free from mineral substance. We may, however, state, that having used this machine for illustrating lectures on electricity for a long time, in daily succession, it was always supplied with water abounding with lime and oxide of iron. Care, however, was always taken to prevent "priming;" and the neglect of that may have given rise to the opinion in respect to the necessity of pure water, to which we have referred.

The effects produced by this machine vary with the pressure, all other circumstances being equal. We have employed pressure varying from thirty pounds on the square inch to that of 120; and up to ninety pounds the spark was in direct proportion to the pressure. Thus, if a spark of six inches was afforded by a pressure of thirty pounds, one of eighteen inches in length was produced by a pressure of ninety pounds; but beyond that pressure the results were uncertain; and, indeed, no further benefit could be observed in that respect.

It must, however, be borne in mind, that the steam was necessarily shut off and thrown on suddenly; and, of course, such tends to increase the evils arising from "priming," in direct proportion to the pressure employed. Full allowance must therefore be made for errors which may thus arise in computing the effect of an increase of pressure. By careful watching, we arrived at the opinion—whether correct or not—that an excess of pressure beyond ninety pounds on the square inch, did not produce any advantageous results.

We have previously remarked, that the length and intensity of spark were modified by shifting the box of metal points nearer to, or further from, the steam issuing from the jets. The effect of these points is simply that of induction—a term which we shall have to explain more fully hereafter. The closer the box of points is to the jet of steam, the longer and thinner is the spark taken from the boiler. When the box is removed to its greatest distance from the jets, then the spark assumes its maximum of density and minimum of length; and in this state is most fitted to charge the Leyden jar, and to produce other effects of what we shall venture to call "condensed" electricity.

A great loss is, of course, sustained by the ascent of hot air from the furnace, which forms the cellular tube of the boiler. This is effected by means of a chimney, which is divided into two parts; one of which is attached to the boiler, and the other is so arranged that it can slide, telescope fashion, into that rising from the boiler. The fuel which is ordinarily used is coke, which has the advantage of producing no smoke, and an intense heat; and the furnace is situated in the centre of the boiler, in an internal flue. Safety-valves and a water-gauge are attached.

The electrical effects produced by this powerful arrangement are of the most astonishing kind. The length of the spark is sometimes nearly two feet, depending on the state of the weather; and during an east wind and intense frost, when the atmosphere is almost destitute of moisture, the maximum effects are produced.

The spark may be obtained from any portion of the boiler, and is received by means of a large brass ball attached to a copper rod. This is connected, by means of wires, with the earth or drain beneath the boiler. A person taking a spark from the boiler, by means of the rod, &c., receives no shock, unless his shoes contain iron nails, when the effect is painful. Few persons would repeat a trial of receiving a spark of two inches in length; and a strong man, who accidentally received one when the steam was issuing at a pressure of ninety pounds, was immediately prostrated, and for some time remained insensible.

In damp weather, it is essential that the glass legs, or supports, be continually wiped between the intervals of the experiments, with dry cloths. This precaution we have already alluded to as necessary with all kinds of electrical apparatus.

Hydro-electric machines, of all sizes less than that we have described, have been constructed. They are, however, dangerous instruments in the hands of incautious persons. The brilliant effects they produce have the tendency of inducing a prolongation of the experiments, until the water in the boiler may be reduced below its proper level; and, in such cases, an explosion is imminent.

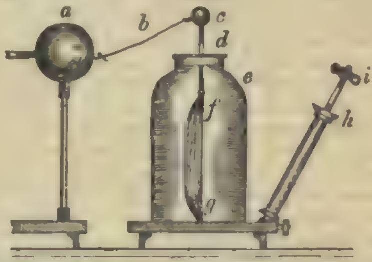
Having described a variety of forms of electrical machines, we shall proceed to investigate the numerous phenomena which may be illustrated by them. As the whole of the experiments we shall introduce are such as we have repeatedly tried ourselves, the reader will have no difficulty in producing the results to which reference will be made, if he follow the directions we shall give him.

THE ELECTRIC SPARK AND BRUSH.

We shall now enter into some descriptions of the different appearances which the electric light presents in the form of a spark or brush, as produced by electrical machines of any kind that we have already referred to. When a metallic wire is placed in contact with the conductor of the machine, all the electrical effects pass off silently, because the wire has sufficient power to convey them away—being what is called a good conductor. If, however, an interval of air be allowed between the wire and the conductor, the charge produced by the working of the machine will not expend itself noiselessly; but owing to the resistance which the air affords to the passage of the electricity, a brilliant spark is produced, the size of which depends on the power of the machine from which it is obtained: a loud snapping sound is also afforded, which increases in intensity according to the quantity of electricity set free. From a small machine, having a plate of a diameter of twelve inches, a spark of one inch in length may be obtained; from one of three feet in diameter, a spark of six inches is produced; and the large plate machine of seven feet diameter, and the hydro-electric, already described, afford sparks varying from fifteen to thirty inches in length, depending on the dryness of the surrounding air.

When a large quantity of electricity is in motion, the spark has a deep-blue colour, and a jagged shape, exactly like a flash of lightning; which it, indeed, really is in miniature. The colour varies according to the medium in which the spark is produced, and also from the substances from which it passes. Some beautiful experiments may be tried by means of an air-pump; and a convenient arrangement is illustrated in the following engraving.

Fig. 6.



a represents the conductor of the machine; *b* is a wire connecting the conductor with the rod *c*; *c*, a rod which fits air-tight in a brass collar, *d*; *d* forms the upper covering of the glass receiver, *e*; *f* is the other extremity of the brass rod, between which and *g* the discharge takes place; *h* is the cylinder of an air-pump, of which *i* is the handle.

With this apparatus the following experiments may be tried:—

Experiment 5.—Having attached the conductor *a* to *c*, draw the rod *c f* so as to leave a space of six or eight inches between its end *f*, and *g*, and exhaust the air from the receiver so as to produce a good vacuum; connecting the air-pump, by means of a wire, with a gas or water-pipe; then commence to work the machine. A spark will pass between *f* and *g*, of a colour which varies according to extent of vacuum in the receiver, *e*. If that be good, a fine purple tint is perceptible: if the vacuum be imperfect, the spark, instead of presenting a continuous discharge, will be intermittent, and of a red colour, attended with sudden star-like flashes and a snapping noise. When the vacuum is good, and the machine of large size, this forms one of the most beautiful experiments in physical science. The spark from the hydro-electric machine, when passed through a tube five feet long and three inches in diameter, produced a magnificent appearance of purple flame, which completely filled the tube so long as the vacuum was maintained. On diminishing this by a gradual admission of air, the continuity of the spark ceased, and intermittent discharges, of a blue colour, were produced. The engraving (Fig. 6) gives an idea of this appearance, so far as shape is concerned, and as it may be obtained by means of a small-sized air-pump.

Experiment 6.—After the air has been exhausted from the receiver, admit, by means of the small screws, a small portion of air, together with the vapour of bisulphite of carbon. This is easily done, by placing a little cotton wool, moistened with liquid, on the screw. The air, rushing in, will take a portion of the vapour with it. The receiver is again to be exhausted, after closing the screw. If the spark be then passed, a fine lavender-coloured discharge will take place; a portion of the vapour will be decomposed; a bright flash of blue light will be seen; and sulphur will be deposited on the inside of the glass receiver.

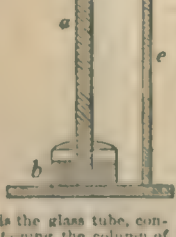
Experiment 7.—By similar means, the vapour of ether, benzole, camphine, alcohol, and other volatile liquids, may be introduced; and each will produce a characteristically coloured spark.

Experiment 8.—Besides volatile liquids, various gases, such as oxygen, nitrogen, carbonic acid, hydrogen, &c., may be employed. This is best done by filling a bladder, provided with a good stopcock, with the gas, and screwing the worm into the screw-hole of the air-pump, through which air is admitted into the receiver. The stopcock of the bladder should at first be closed, until the air in the receiver has been exhausted; a small quantity of gas may then be admitted by opening the stopcock. The spark is then passed as before, and some pleasing effects may thus be obtained.

We must caution the experimenter, however, as to the employment of coal gas, or pure hydrogen; as, if the receiver happen to contain air, or if the gas be mixed with air in the bag, the electric spark may cause its ignition, and an explosion may ensue.

Experiment 9.—A very ready mode of trying these experiments in a vacuum, may be found in an ordinary barometer tube. A glass tube, thirty-six inches long, and a quarter of an inch in diameter, is to be sealed at one end, and through this a platinum wire is to be passed, so that one end may be inside, and the other outside of the tube. The latter is to be filled, at its open end, with mercury; and the finger being placed on the hole, so as to prevent the escape of the metal, the tube is to be inserted into a small vessel containing mercury. The finger may then be removed from the tube, and a portion of the metal will run out into the cistern. The height of mercury remaining in the tube, will correspond with that of an ordinary barometer, and a vacuum will be left at the top of the tube. The platina wire is then to be connected with the conductor of the machine, and any liquid or gas can easily be passed up to the vacuum portion of the tube, by means of its open end. We first employed this arrangement for experiments with a Rhumkorff coil machine, and found it extremely convenient; because, excepting the presence of a slight amount of mercurial vapour, a perfect vacuum is readily obtainable. Fig. 7 represents an apparatus of this kind.

Fig. 7.



a is the glass tube, containing the column of mercury; *b*, the cistern of that metal; *c*, the vacuum; *d*, the platinum wire; and *e e*, a ring-stand to support the tube in a vertical position.

We shall have again to refer to this arrangement when we explain the cause of the Aurora Borealis; but we may just remark, that the electrical discharge in a vacuum, presents many points of resemblance to the phenomena we have named.

The reader, on repeating the experiments we have suggested, will at once perceive the truth of what we before stated—that the colour and intensity of the electric spark depend on the density of the medium through which it passes: and having illustrated this fact, we may now suggest a variety of experiments, which present the spark as it passes between conductors. A great number of ingenious devices have been arranged for this purpose.

Experiment 10.—Paste, on a piece of window-glass, some small dots of tinfoil, in the manner illustrated in Fig. 8, so that a continuous and equi-distant series may pass from one end to the other; attach to one end a wire, connected with the earth, and present the opposite end to the conductor of the machine. At each interval between the pieces of tinfoil, a spark will pass as the electricity breaks from one to the other through the air. Any device may thus be made luminous by the electric discharge; and an illustration of one of these arrangements is found in Fig. 9.

Fig. 8.

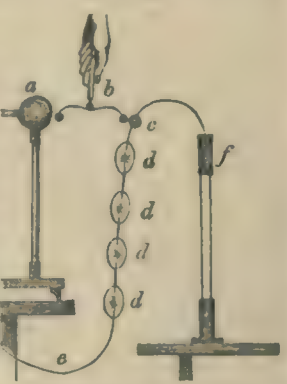
Fig. 9

A brass knob should be attached to that end which is presented to the conductor, for reasons we shall presently explain.

Experiment 11.—A very pretty mode of showing the electric spark, is that of threading, alternately, glass beads, with pieces of cork covered with tinfoil, on a silk thread previously varnished. One end of this is to be connected with the earth; and the opposite one, being terminated with a brass ball, is to be presented to the conductor of the machine. As the spark passes, each bead will appear luminous. A thread of upwards of 100 feet long was frequently used with the hydro-electric machine, when many hundred sparks, passing over the whole length, produced a most brilliant effect.

Experiment 12.—Those of our readers who possess a three-feet plate machine, may make a very elegant arrangement for exhibiting the spark passing inside egg-shells. Four or six egg-shells are attached to each other, so that a copper wire may pass through the end of each. The wires are separated, at the centre of the egg, by a thin thread of silk being tied to each, so as to preserve the mechanical continuity of the chain whilst the electrical continuity is broken. On presenting one end of the arrangement, by means of a knob, to the conductor, each egg will be beautifully illuminated as the spark passes between the wires inside it. The arrangement is illustrated in Fig. 10.

Fig. 10.



a is the conductor of the machine; *b* is a discharger, through which the spark passes to *c*; *d d d d*, are four eggs, through which the spark passes; *e* is a wire connecting them with the earth; *f*, a stand of glass rod, to support the eggs.

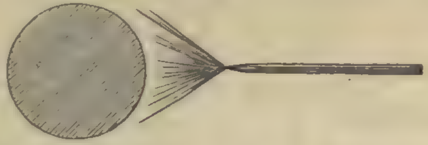
In each of the experiments suggested, we have recommended, that one end of the apparatus should have a brass ball attached to it; or, what will do equally as well, one of cork, covered with tinfoil; and that this ball should be held at a small distance from the conductor. This plan has the effect, apparently, of (what we shall call, for want of a better term) giving an impetus to the charge. If any of the arrangements we have described are placed in direct contact with the conductor, the effect is very feeble.

This leads us to remark on the result which points have on the passage and character of the electric spark. When any pointed object is presented to an electrised surface, the spark does not pass in the manner we have previously spoken of, but becomes converted into a brush-like form; hence the term "electric brush."

Experiment 13.—Present a penknife, or pointed brass rod, to within a short distance of the conductor of the machine. A peculiar hairy-like spark will be produced, having an appearance illustrated in Fig. 11.

Points have exactly an opposite effect on the electric force, to that of round and even substances. They tend to diffuse the force; and hence the conductor of the electric machine is always well rounded and polished in every part, to prevent the loss of electricity. For the opposite reason, lightning conductors (of which we shall speak fully hereafter) have their extreme end, towards the sky, always pointed. A very instructive experiment, illustrating the property of points, may be tried as follows :—

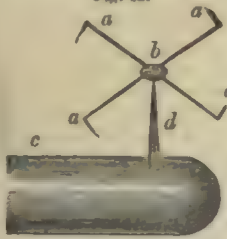
Fig. 11.



Experiment 14.—The machine being in good action, and affording large sparks between the conductor and a brass knob, place a sod of grass on the conductor itself. On presenting the knob, no further spark can be obtained, because the points of the grass leaves radiate and diffuse the electricity. The grass of the fields thus exercises a wonderful effect on the electrical state of the earth.

An ingenious arrangement of points, which are fixed to a common centre, and free to rotate on a point fixed in the conductor of the machine, exhibits another effect of pointed surfaces; which is, that a current of air is driven from them on the electric discharge taking place. One of these is represented in Fig. 12, in which *a a a a* are the pointed wires, fixed in a common centre *b*. *c* is the conductor of the machine; and *d* a pivot on which *b* can rotate. Now, not only will such an arrangement afford a current of air at each point—which may be tried by holding a lighted candle thereto—but the wheel will speedily turn round, owing to the mechanical action which is generated by the electric force against the surrounding air; and at each point a brush-like flame will be seen. This arrangement has been termed the "electric windmill."

Fig. 12.



Experiment 15.—The current of air produced from a pointed body attached to an electrical surface, may be noticed by fixing a pointed wire to any part of the conductor. If the machine be then set into action, and a lighted candle be held before the point, the flame will be rapidly driven away.

The reader, having thus seen the diffusive power which pointed bodies have on electrified substances, will at once perceive the necessity which exists for all the parts of the machine being kept as free as possible from dust; because each particle acts precisely in the same way as the pointed wires, &c., of which we have been speaking.

By other arrangements, many interesting experiments may be tried with the electric spark, as taken from the human body, &c. For this purpose, an electric stool will be required; which is easily made, by fixing into a piece of wood, previously well dried by heat, four rods of glass, to serve as legs, in place of wooden ones. Another mode is, that of resting a square piece of wood on four glass wine-bottles, which, as bad conductors, prevent the escape of electricity from the person standing on the stool. A sheet of gutta-percha, which also is a bad conductor, may be placed on a block of dry wood; and such often answers the purpose of an electric stool; the object being to interpose, between the earth and the individual, some non-conducting and insulating body. A wire is then connected with the conductor of the machine, and its other end is held in the hand of the person standing on the stool. The machine is then to be worked; and the following experiments may be tried :—

Experiment 16.—Instead of presenting a brass ball to the conductor, as mentioned in Experiment 14, hold one near to the hand of the electrified person, and a bright spark will pass. Indeed, the body becomes, for the time, an extension of the conductor of the machine.

Experiment 17.—Present a metal spoon, filled with ether, to a brass ball, held in the hand of the person on the stool. When the spark passes, the ether will be inflamed.

These experiments may be varied in many ways, and they will be sufficient to show the manner of conducting others. We must, however, caution our readers not to take strong sparks from the eyes or head, as such may prove exceedingly harmful. A spark passing from the body of a person electrified by the hydro-electric, or large plate machine, has so powerful an effect on the system, as to produce a shock which would prevent the individual from choosing a repetition of the experiment.

We must, of course, here confine our attention to the spark produced by frictional electricity. We shall find, when we treat on voltaic and magneto-electricity, that the light, and general luminous effects produced thereby, are much different from those to which we have been referring, owing to causes which we shall then explain.

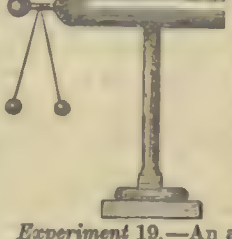
ATTRACTION AND REPULSION.

HAVING chosen first to speak of the electric spark, because it naturally attracts the attention of the experimenter, and paves the way for more intricate and interesting electrical phenomena; we shall now consider two effects which present themselves when bodies are electrified—namely, those of attraction and repulsion.

It has already been mentioned, that an electrified body has the power of attracting light substances to its surface.* Thus, if a piece of dry window-glass be placed at a distance of half an inch from, and over, some pieces of paper or feathers, and its upper surface be briskly rubbed by means of a silk handkerchief, the feathers will dart up, and adhere for a short time to the under surface, until, being electrified equally with the glass, they will be repelled from it, and fall again to the place on which they had previously rested. We shall suggest a few experiments illustrating both attraction and repulsion, before entering into the laws which govern the phenomena.

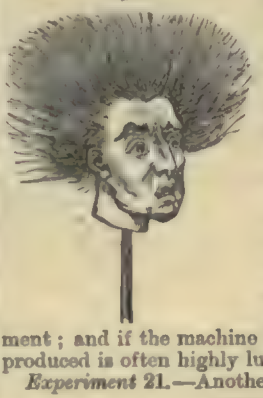
Experiment 18.—Hang two small pieces of pith, obtained from the elder-tree, by means of a silk thread, from the conductor of the machine, so that they may rest against each other. On working the machine, they will be similarly electrified, and will repel each other so long as they continue in that state. On presenting the knuckle, or a brass ball to either, they will fall together again, owing to their electric equilibrium being restored. The mode of conducting this experiment is illustrated in Fig. 13.

Fig. 13.



Experiment 19.—An amusing arrangement is sold by the instrument-maker; in which a head of hair is employed. It is to be fixed by means of a brass rod, in an upright position, on the conductor of the machine. So long as it is unelectrified, the hair rests naturally about the head; but on working the machine, each hair becomes similarly electrified, and so repels its neighbour in the manner shown in Fig. 14.

Fig. 14.



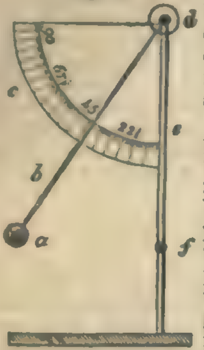
Experiment 20.—Let a person stand on the glass stool; and having combed out the hair of his head, connect him, by means of a wire, with the conductor of the machine. Each hair will separate, as in the last experiment; and if the machine be in good action, the effect produced is often highly ludicrous.

Experiment 21.—Another mode of showing the effect of repulsion, is that of attaching a number of narrow strips of tissue-paper to the conductor of the machine. When electrified, they will all separate, as in the two last experiments.

---

* See *ante*, p. 167.

Fig. 15.

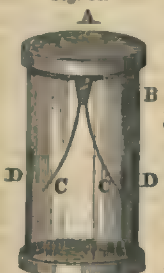


a is a pith ball suspended by means of a straw, *b*, to a pivot at *d*, on the upright stand, *e*; *c* is a quadrant graduated to 90°; *f* is a small ball attached to the upright stand.

Electroscopes have been constructed, which are intended to show the presence of free electricity. They are chiefly of two kinds—the pith ball and gold-leaf electrometers, as they are sometimes also called. The former alone deserves that name, because it registers, by the extent of repulsion indicated on a graduated quadrant, the amount of free electricity present. Its construction is as follows. (See Fig. 15).

Now, when this electrometer is placed in contact with a non-electrised body, the ball, *a*, will rest in contact with *f*; but if the body be electrified, then *a* will be repelled from *f*, and will rise towards the top of the quadrant, just in proportion to the amount of free electricity present: the number of degrees marked on the quadrant, by means of the straw attached to the pith ball, of course indicates the extent of electrisation.

Fig. 16.



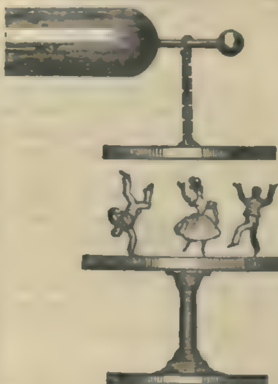
Such an instrument, whilst acting tolerably well when a large amount of free electricity can be observed, is of far too coarse a nature for detecting minute electrical disturbances; and, for this purpose, the gold-leaf electroscope is of great value. One of these is represented in Fig. 16; in which A is a brass cap, fitting on a cylindrical glass vessel, B; C C are two pieces of gold-leaf, suspended from the brass cap; D D are pieces of tinfoil, pasted on the opposite sides of the glass cylinder. Now, so long as the brass cap is not electrified, the gold leaves, C C, hang together in contact; but on presenting any electrified body to A, the leaves immediately repel each other, even although the free electricity is extremely slight in quantity. We should, however, state, that the indications of this instrument entirely depend on the state of the glass cylinder. If this is in the least dirty or moist, the electricity at once passes away. This electroscope must therefore be carefully dried before use, and should be slightly elevated in temperature beyond that of the surrounding air.

An instrument of this kind is easily made by employing an ordinary gas chimney-glass. In the inside, to about half its length, two narrow strips of tinfoil are to be pasted opposite to each other; the bottom of the glass should then be closed with a cork. Into the top, another cork, *entirely covered with tinfoil*, may be fitted; and to the inside of this, two strips of gold-leaf are to be attached, so that they may hang inside the glass with the lower end a little below the top of the tinfoil strips, as shown in Fig. 16. Such an instrument, if carefully made, will answer every purpose which can be required for many delicate electrical experiments.

Various forms of electroscopes and electrometers have been devised, each being suited to some special purpose. Amongst the most delicate of these is that invented by Professor Thomson, of Glasgow; which was used during the laying of the Atlantic telegraph. Its peculiar construction prevents the possibility of illustrating it by an engraving: we may observe, however, that its indications of the feeblest electrical disturbance, makes it of great value in many investigations.

Generally speaking, electrical attraction and repulsion are coincident. The reason of this we shall understand better when we examine into the opposite electrified conditions which bodies assume, and which have been termed positive and negative. For the present, we shall only illustrate the phenomena, without entering deeply into their causes; and adduce some experiments illustrative of attraction.

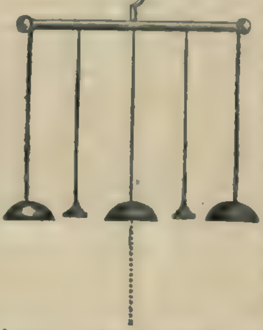
Fig. 17.



If a metal plate be hung from the conductor of the electrical machine, and some pith balls be placed within two or three inches of it, they will be attracted towards the plate. An amusing mode of showing this is illustrated in Fig. 17; in which we observe a stand for holding figures of men, &c., cut out of pith, for the sake of lightness. At a distance of three or more inches, the plate from the conductor is suspended. On working the machine, the figures will commence dancing between the plates, owing to the electrical attraction and repulsion which ensues.

Another mode of showing the same effects, is that of the electrical bells. The arrangement consists of three bells and two clappers, suspended from a beam, which is to be attached to the conductor of the machine. The bells are electrified whilst the clappers oscillate between them; and so long as the machine is worked, a continual ringing of the bells takes place. A chain is hung from the centre bell, so as to communicate with the earth. The ordinary form of this apparatus is shown in Fig. 18.

Fig. 18.



Electrical see-saws, &c., are constructed by the instrument-makers, for illustrating the general laws of attraction and repulsion.

The intensity of these forces varies inversely as the square of the distance between the electrified body and that on which the attractive or repulsive effect takes place; and this law agrees with that governing all radiating forces, as we have previously explained in our sections on heat and light. There are, however, so many interfering causes which disturb the exactitude of an experimental illustration of this fact, so far as electricity is concerned, that whilst, as an inference, we may entirely trust to its truth, we have not such rigidly-founded premises and conclusions as we can obtain when investigating the other undulatory forces.

CONDUCTION.

We have already stated, that all bodies have, electrically speaking, been divided into two classes—namely, conductors and non-conductors; or, what is equivalent thereto, electrics and non-electrics. This distinction, however, has been made without any title to correctness; for we are acquainted with no body which will not, to some extent, however trifling, conduct electricity; and, on the other hand, we can never call any body incapable of affording evidences of free electricity, when proper means are employed to that end. We shall therefore use such terms with the limitations we have named, and as expressions which, whilst they assist to convey definite ideas to the minds of our readers, are not to be considered as incorporating the real facts of the case.

By the term "conduction," we mean that ability which some substances have, of exhibiting, at a distance from its source, certain effects of any force which seem to be conveyed on their surface, or by their mass. The relative power of such substances is measured by the rapidity with which these effects are shown when one body is compared with another in that respect. Thus, a piece of wood, six inches long, may be in a rapid state of combustion at one of its extremities, whilst, at the other, not the slightest sensation of heat can be experienced. A piece of copper, of the same size, will, however, produce a very different result; for if one end be heated but moderately, the calorific effect will be speedily evidenced at the other end—showing that the principles of heat, or its effects, travel much more rapidly from one extremity of the metal to the other, than is found in the case of wood. Now, the metal is therefore termed a good conductor, and the wood a bad one; or sometimes, erroneously, a non-conductor.

Generally speaking, there is no great difficulty experienced in deciding on the relative electric conducting power of a body. The effects of free electricity can be easily observed by means of electroscopes, &c., even when the amount present is but very slight. In the case of heat and sound, our means of detection are not so delicate; and, therefore, a list of conductors is less to be relied on. On the other hand, the electrical indications rapidly exhibit themselves and pass away, and, for that reason, are sometimes but slightly appreciable at a distance from the source of disturbance. With respect to electricity obtained by friction—glass, resins, sulphur gutta-percha, fur, hair, and similar bodies, are included amongst bad conductors, because they have very little tendency to permit the passage of electricity over them. Possibly, for this reason, they most readily exhibit electrical effects when submitted to friction; and hence have been termed electrics. The metals, in the order of gold, silver, copper, platina, brass, iron, &c., are excellent conductors of electricity, and, accordingly, are employed whenever its effects are required to be shown at a distance from its exciting cause. Another class, standing intermediate between good and bad conductors, embraces fluids of various kinds, moisture, &c.; which, according to circumstances, more or less readily permit of the passage of electricity. We have often spoken of the necessity which exists of keeping every part of electrical apparatus free from moisture; and this is simply because its presence on the surface of non-conductors, such as glass, &c., actually has the effect of rendering them, superficially, tolerable conductors.

By way of parenthesis, we may observe, that it is a good plan to cover the legs and supports of electrical apparatus with a solution of shell-lac, or best red sealing-wax, in spirits of wine. This forms a coating, which has not so great a tendency to condense moisture as glass; and, in damp weather, its advantages are greatly felt by the electrician. This resinous coating is a worse conductor of heat than glass; and it and gutta-percha, for that reason, may at all times be employed for insulating purposes.

With respect to the mode in which electrical effects travel over, or are conveyed by, conductors, we may observe, that, unlike heat, which travels in the mass of a body, electricity seems conveyed only by their outer surface. Hence, within certain limits, a large surface of a comparatively bad conductor, may act as efficiently as a small mass of a good conductor. We have thus observed all the expected effects of a seven-feet plate machine, or of the hydro-electric, entirely dissipated by a damp glass surface; whilst the same quantity of electricity, sent through a solid but fine metallic wire, would have instantly reduced it to a melted state, or dispersed it into fragments. It is thus of extreme importance, in employing conductors for protecting buildings from lightning, that the double condition of surface and solidity should be attended to. In experiments with large electric and voltaic batteries, we have, for many years, preferred the use of flat copper strips to that of wire of the same weight, but, of course, exposing less superficies. And, at the present day, flat copper bands are preferred as lightning conductors, in the navy, to copper rods which had been previously used.

The continuity of a conductor, if broken even to the smallest extent, destroys its efficiency. We shall, however, defer considering this element, until we examine the mechanical and other effects of intense charges of electricity, which will come under our notice when we speak of the Leyden jar. We have already stated our preference, at all times, for the use of wires to that of chains, in connection with electrical experiments; and this arises, experimentally and theoretically, from the facts which we are here mentioning. As a powerful charge passes over either a brass or iron chain, a spark may be noticed at every link, indicating, that there the continuity of conduction is broken, and that the force has, so to speak, to "leap over" an obstacle. Besides, at each break there is a tendency to diffuse electricity, and hence a decided loss of power ensues.

The conducting power of bad conductors is modified by heat; hence, heated glass and air become better conductors than when they are at ordinary temperatures. This fact should be borne in mind in warming and drying electrical apparatus; and their temperature should only slightly exceed that of the surrounding air, so as to prevent the deposition of the moisture, by condensation, on their surface.

Some very remarkable effects may be noticed when a powerful electric charge passes by a good conductor. We have observed, that the external surface of a metal may be actually fused, whilst the internal mass is entirely unaffected. It often happens that metallic objects, in the pockets, &c., of persons struck with lightning, have been externally fused; but this generally occurs where no continuous conductor for either heat or electricity is present. We can only explain this by suggesting, that the development of each force is very sudden, and yet only affects the extreme outer portion of the metal, the mass of which speedily absorbs the intense heat which has been generated.

Circumstances occur in which a tolerable conductor may become an excellent electric; and the most extreme case we can point out is that of water. This liquid, in the state of fine particles, spread dew-like over a bad conductor, as we have already seen, improves its conducting power; yet, in exactly the same state at the nozzles of the hydro-electric machine tubes, it affords, by friction, an enormous amount of free electricity.

From these facts, our readers will at once see, that the idea of conduction and non-conduction can only be sustained in a relative or comparative point of view, and that special circumstances can entirely modify, and occasionally change, the character of any substance or liquid. There, however, exists great analogy between heat and electricity in this respect.

ELECTRICAL THEORIES.

For the sake of simplicity, we have hitherto restricted our observations to such facts as could be explained, under the idea that electricity, like heat, could be conveyed to any place; was diffusible, and, generally, had the characteristics of what we may term a single acting force. We carefully abstained from mentioning, that certain theories which have been, and are strongly maintained, entirely militate against that notion. This course has been adopted because it permits the reader to become acquainted with facts sufficiently plain to explain themselves, and so a kind of foundation has been laid for the more complicated structure of phenomena and laws which we shall now begin to examine.

The earlier electricians were of opinion, that an electrified body differed from a non-electrified one, by containing a greater quantity of electricity in a free state. In other words, an electrified object had an excess, whilst the non-electrified had a deficiency, of the electric force. Hence, the terms positive and negative were continually employed, in their strictly mathematical sense, to express such an idea; and we may, perhaps, still further illustrate the position by referring to the ordinary process of addition in algebra, whereby numbers of different signs, on being added together, give a total value midway between their individual amount. Thus, the addition, algebraically, of $+a$ to $-a$, would afford nothing in amount. In the same way, electric equilibrium was similarly considered as existing in bodies at zero, whilst its disturbance was simply an addition to the electrical quantity of bodies in a positive electrical state, and an abstraction from those which assumed the negative condition.

This has been termed the single theory; and so extensive was its employment at one time, that all its terms are still to be found in electrical works and lectures. Indeed, it is often a matter of considerable amusement to a strictly philosophical person, to hear those who strenuously adopt the double theory, using constantly such terms as "current," "passage," and the like, which can only properly be used under the supposition that a single electric force exists.

We shall find, however, that although the single theory has the advantage of great simplicity, and ready adaptation to *nearly* all the circumstances of electric disturbance, it yet fails to explain some of the most important phenomena, especially such as are involved in electrical induction.

The double theory supposes the existence of two electricities, exactly opposed to each other in every respect, just as we observe in the opposite poles of a magnet. When electricity is excited, this theory supposes that the two electricities are parted; that they have a mutual tendency to recombine; and that all electric phenomena result from one or other of these tendencies, and, generally speaking, from the combined action of the two.

In the double theory, the terms "positive" and "negative" are used in a *physical* sense only. They express no idea of quantity, but rather of position. The opposite electricities, indeed, are supposed to be exactly equal in quantity and intensity; and this is one chief cause of their constant tendency towards recombination, and, consequently, to reproduce the natural or normal state of all bodies in an unexcited state, electrically speaking. The distinction has been carried even still further; and the terms "vitreous," or "glass," and "resinous," or "rosin-produced" electricities, are employed, for reasons which will be best explained by our readers trying the following experiment.

Experiment 22.—Suspend a feather, by means of a silk thread, so that it may hang freely, and at a distance from any other substance. Let an excited glass tube be brought near it, when the feather will be immediately attracted, and afterwards repelled. Remove the glass tube, and then present a roll of sealing-wax, which has been rubbed with a dry flannel, and the feather will immediately fly towards the wax.

This would be explained, under the *single theory*, by saying that the glass had positively electrified the feather, and that the wax, being in negative or deficient electrical state, had attracted, and so the excess of electricity of the feather had combined with the deficiency of the wax, and an electrical equilibrium had thereby been restored.

Under the *double theory*, we should say, that the *vitreous kind* of electricity of the excited feather combined with the *resinous kind* of the wax, and hence the result. Our readers will thus perceive, that the most simple way of placing before them the antagonism of the two theories, is that of assigning quantity as the leading feature of the single, and kind, or quality, as that of the double theory. That similarly electrified bodies repel each other, is, of course, admitted by the advocates of each theory as a fact; but the cause each assigns is in accordance with that adopted to explain the results of our last experiment.

We do not intend to take our readers through the almost interminable arguments which have been used on both sides. It has been our good fortune to have read most of the works, and to have heard the public lectures, of the leading electricians of the day; and the only conclusion at which we have arrived, is, that whilst the subject in dispute has strong and able arguments on either side, those who take part in it are almost constantly led to compromise their views as some occasional or accidental circumstance arises. As we before observed, the employment of the terms of each theory, indifferently at least, indicates extreme uncertainty as to the real state of the case.

However, the double theory is the most usually recognised at the present day; and we shall use it in explaining many of our future experiments. The strongest objection which suggests itself to our mind is, that it has no analogy to the theories of the other undulatory forces. It is true that magnetic phenomena countenance the idea; but we must bear in mind, that the connection of magnetic and electric affections is so intimate, as to leave us scarcely room to doubt whether any difference really exists. If, however, we compare the double theory of electricity with our theories of heat and light, the analogy at once fails; and no one has yet been bold enough to suggest the idea that there are two kinds of heat or two of light. The investigations which have lately been made into the correlation of forces, certainly tend to induce the adoption of the single theory. However, this is one of a class of subjects which can only be properly understood by a much more extended knowledge of force, motion, and matter, than we at present possess. We shall, therefore, refrain from urging any further views on the subject upon our readers; and having endeavoured to state the case fairly, shall make free use of each theory, in our future pages, as convenience of expression or illustration may render desirable. We shall thus stand free from the charge of inconsistency or dogmatism.

It will now be proper that we should examine the doctrine of electrical induction, and use the Leyden jar and battery for the purpose of illustrating it.

INDUCTION—THE LEYDEN JAR AND BATTERY.

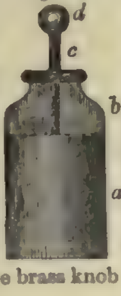
In attempting to convey an adequate idea of the phenomena included in electrical induction, considerable difficulty arises, because there is no analogy to which we can refer, except that of magnetic phenomena, which can assist us only to a limited extent. We shall, therefore, rely on a careful and attentive study on the part of our readers, if we endeavour to present to them, as far as possible, a logical exposition of the doctrines or laws which modern science has determined to be the basis of this department of natural philosophy. The term "induction" has been chosen by electricians as expressing a similar idea, in electric science, to that which the same word would convey in the conversation of daily life.

We endeavour to induce a person to fall into our ideas by presenting him such facts or arguments as will be sufficient to bring him into our mode or course of thoughts. Similarly, when we wish to induce a certain electric state in any body, we present such an electrified condition as will produce the effect we desire. There is, however, this difference—we produce an exactly opposite state to that we present; because, if we electrify any body positively, we intend to produce on its surface a negative electrical state, and *vice versâ*. Hence, we depend on the fact, that action and reaction are not only equal, but that they, in certain cases, are naturally producible. Our readers will more fully understand our statements when they reduce them to a practical form by actual experiment.

The most eligible instrument we can choose for the purpose of illustrating our subject, is that of the Leyden jar and battery. The early experimenters in electrical science, were not acquainted with the fact, that a greatly increased effect might be produced by means of an arrangement such as that to which we allude. It is stated, that the discovery was accidentally made by M. Muschenbroeck, who, having allowed a chain from the conductor of an electrical machine to rest inside a glass vessel partly filled with water, whilst his hand encompassed the outside, was astonished at receiving a powerful shock on attempting to remove the chain from the vessel. The occurrence, or, at all events, its repetition, in the town of Leyden, has given a name to the arrangement.

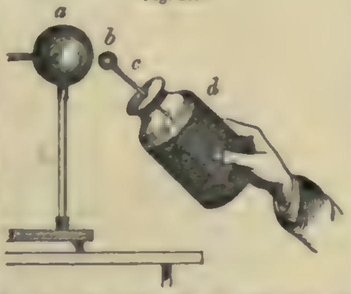
A Leyden jar is easily made by coating any kind of thin glass vessel with tinfoil, on both sides. They are usually cylindrical glass jars, on the outside and inside of which tinfoil is pasted to about two-thirds the height. The reason the coating is not carried higher, is, that the charge would rapidly discharge itself if the two coatings were not separated to some distance. The bottom of both, in and outside, should be also covered with foil. The coatings are simply required as distributors of the electricity, and, as such, only are they essential. It is well that the reader should bear this in mind, because many persons imagine that the charge rests in or on the tinfoil, instead of the glass. So far from this being the case, a jar may be fitted with movable coatings, which, after charging the jar, may be removed by means of silk threads, and it will be found that the charge is actually retained on the surface of the vessel. On the top of the jar a wooden cover is placed, the object of which is to keep out dust, &c. Through the cover a wire is passed, which communicates with the inside metal lining by means of a chain. The wire also extends outwards, beyond the top of the cover; and at its extremity a brass knob is placed, at which the charge is taken from the conductor of the electrical machine. Fig. 19 represents the usual form of the Leyden jar: *a* is the outside coating of tinfoil; *b* is the interval of glass between the inside and outside coatings; *c* is the wire which extends into the jar; and *d* is the brass knob at which the charge is received.

Fig. 19.



The annexed engraving (Fig. 20) illustrates the mode of charging the jar; *a* being the conductor of the electrical machine; *b* the knob of the jar; *c* the wire reaching into the inside; and *d* the outside coating. The jar may be held in the hand whilst being charged, and a wire should be attached to its outside so as to maintain connexion with the earth, for an insulated jar cannot be charged.

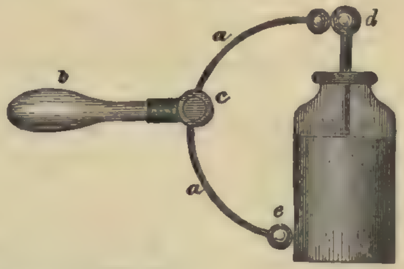
Fig. 20.



The length of time required to charge the jar, depends on its size and the power of the electrical machine; for a small one—say of twelve inches in the plate—will not fully charge a jar of large size. A seven-feet plate machine, or the hydro-electric, will easily charge thirty jars, two feet high and twelve inches in diameter, in one minute or less; and a single jar, of the same size, can be charged several times per minute, by either the plate or steam machine.

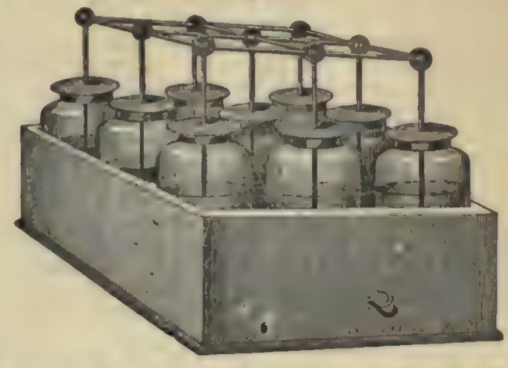
If a jar be presented too long to the conductor of a machine, it will discharge itself; a brilliant spark, attended with a loud, snapping noise, will take place; and it is more than likely that the discharge will force itself through some portion of the glass, and so render the jar useless for further experiments.

Fig. 21.



The usual mode of discharging a jar is represented in the following engraving. An instrument, called a discharger, is employed, which consists of two brass knobs, fixed to a bent wire, *a a*. The instrument is held by the glass handle *b*, and the wire is fixed on a joint *c*, by means of which the two balls can be removed from each other to any extent which may be desired. The jar being charged, the balls of the discharger are brought into contact with the knob, *d*, of the jar and its outside coating, *e*, when a spark and a snap will be produced; and the electric equilibrium will be restored in a small jar, and nearly so in one of large size. In using the latter, a slight second discharge may occasionally be observed, which arises from what is called the residual charge. In very dry, frosty weather, we have found that very large jars will actually charge themselves—a fact which we first became acquainted with by removing one whilst holding the knob and the outside coating at the same time. This, however, is a rare occurrence, because, unless a Leyden jar is kept very clean and dry, dust and moisture soon settle on the glass surface, and so prevent the electrical separation of the two coatings. In frosty weather, and during a dry east wind, some curious results are often obtained from Leyden jars; and it is a good rule to apply the discharging-rod to every part of an insulated coating before setting the apparatus aside, because the charge will sometimes remain for days on its surface. Large jars have the necessary disadvantage of being made with thick glass, which prevents their being readily charged. They, however, must be used for large machines. It is usual to connect a number of either the large or small size together, when powerful electrical effects are desired. Such an arrangement is called a Leyden Battery; and by its use some most interesting natural phenomena may be readily illustrated. One of these is represented in the following engraving; in which it will be observed, that all the insides are connected together by means of rods which are fastened to the knobs of the jars, and the outsides rest in a box lined with tinfoil, by means of which they are all, electrically speaking, joined together. It is advisable, however, to fix a wire so that it may pass round each jar, and it should be extended to a gas or water-pipe, so as to ensure the ready charging of the jars. In Fig. 22, this is effected by means of a wire attached to the hook in the side of the box. A rod should extend from the knobs of the jar to the conductor of the machine; and thus the battery is to be charged. The mode of discharging it will be noticed as we proceed with our experiments. We should here state, that unless the single jar, or each one in a Leyden battery, is kept perfectly free from dust and moisture, it is impossible to charge them. They should be carefully wiped with a warm silk handkerchief before use, and heated to a little beyond the temperature of the room in which the experiments are to be tried; and it is also frequently

Fig. 22.

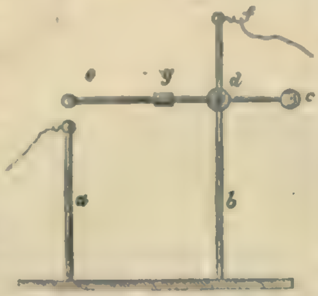


necessary to wipe them when in use, as they often gather dust on their surfaces by the electrical attraction which is produced as they are charged.

It is often a matter of surprise to observe the quantity of dust which collects on a charged surface; the effect of which is to much diminish the power of both the machine and battery.

A very convenient form of discharger for powerful batteries is represented in Fig. 23. It has the advantage of discharging the battery at any period, or at any amount of charge the experimenter may choose. It consists of two upright glass rods, *a* and *b*. On *a*, a brass knob and hook are fixed, from which extends a wire to the outside of the battery, or to any intervening piece of apparatus, and thence to the outside of the battery. *c e* is a rod of brass, moving readily on a pivot, *d*; and *g* is a sliding weight, by means of which the balance between the knobs, *c* and *e*, can be adjusted. The knob, *c*, tends to raise *e* upwards; but by shifting *g* from *d* to *e*, the amount of charge in the battery can be regulated. The inside of the battery is attached by a wire to the hook on the knob *f*. The engraving represents the arrangement as if a battery were being charged. When it is fully so, the knob, *e*, will fall down towards that on the rod, *a*, and the discharge will at once take place. We need scarcely state, that the principle on which this arrangement works, is that of electrical attraction between the charged knob, *e*, and that fixed on *a*. Besides the convenient character of this apparatus, it prevents the unpleasant and, possibly, dangerous effect which might arise when a large battery is discharged by means of the discharger previously described.*

g. 23



It is, however, occasionally necessary to use a hand discharger; and the handle for that purpose should be a glass rod, not less than two feet in length, so as to prevent risk of accident.

We know of no better mode of regulating an electric charge in a battery, than that we have just described, and which we always prefer to use. Many others have been proposed, but as they present no special advantage, we shall refrain from describing them.

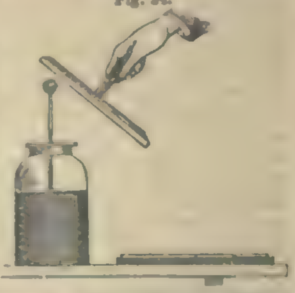
To assist those who may not be able to purchase extensive apparatus, we shall give directions by which they may succeed in constructing a Leyden jar; and by using the electrophorus, previously described,† they may easily try several of the experiments we are about to suggest.

A Leyden jar may be made by half filling a thin, round glass phial with brass or iron filings. A cork is then to be fitted into its neck, and a wire should be fixed in the cork, so that one end may enter the filings, and the other should extend two inches beyond the neck of the bottle. On the outer end of the wire a brass knob is to be fixed, or, what answers equally well, a round cork covered with tinfoil. The outside of the phial is to be coated with tinfoil to half its height, and the bottom should be similarly covered. The arrangement, though somewhat rude in its construction, answers remarkably well.

Such a jar may easily be charged by means of the electrophorus, which must be first excited, as already directed.‡ The cover is then to be brought to the knob of the jar, when a spark will pass. This is to be repeated until the jar is charged, which may speedily be done with one of the kind we have just described. The method of thus charging a jar with the electrophorus, is illustrated in the following engraving.

Having described the apparatus which will be required for illustrating the laws of induction, &c., we shall enter into an experimental investigation of them, and also illustrate the luminous, calorific, mechanical, and other effects of a high charge of electricity.

Fig. 24.

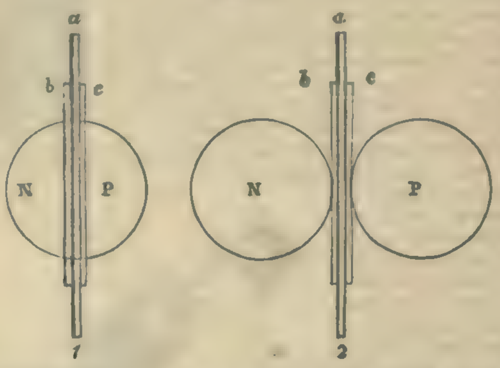


When a Leyden jar is charged by presenting the knob to the conductor of an electrical machine in action, the natural equilibrium of the latent electric force is at once disturbed, and the surfaces acquire what may be termed a polar state. By this we mean, that a new and active condition of force is induced, by which the hitherto quiescent and inactive conditions of the latent electricities are placed in opposite positions to each other, and yet having a tendency to recombine.

This may be better understood if we employ a diagram illustrating the changes which take place on the glass surfaces; and instead of using the ordinary Leyden jar, we shall suppose that we have, coated on each side with tinfoil, a piece of window-glass. A Leyden jar, in fact, may be regarded as such—a piece of glass bent into a cylindrical form. We shall also confine our attention to one small point on its surface, as such, of course, illustrates all that takes place in the entire jar whilst being charged and discharged.

In Fig. 25 we have two diagrams, of which No. 1 is intended to represent a jar or piece of coated glass, in its natural state; and No. 2 illustrates the electrical change which takes place when the jar is charged. *a* is the glass plate, and *b c* are the tinfoil coatings. In No. 1, we observe a circle illustrating an electric equilibrium, in which the negative and positive, or vitreous and resinous electricities, are in a state of combination. In No. 2 we observe the effect of charging the jar, which results in the separation of the two electricities, by which a polar state is induced, and each side of the glass plate becomes in an opposite electrical state.

Fig. 25.



If a metallic or other good conducting communication be made between *b* and *c*, in No. 2, the two electricities will recombine, the polar state be lost, and the coated surfaces return to a state of equilibrium, such as at first was spoken of, and shown in No. 1.

We therefore observe, that the primary effect of charging a glass surface, is to put the natural electric state of repose into an active condition; and this results in the separation of the two electricities, and their individual appearance on each side of the glass plate, which we have supposed to be infinitely thin, and to have undergone no electrical change of any kind in its mass or substance.

We need scarcely observe, that the explanation we have given is that arising from the employment of the double electric theory. If, however, we suppose the existence of only one kind of electricity, then we shall explain the changes which occur by stating, that each side of the charged plate becomes polar; but that the positive side has an excess of electricity, whilst the negative one becomes deficient in that respect. These two states are occasionally represented by the mathematical signs of + and — (*plus* and *minus*).

---

* See *ante*, p. 178. † See *ante*, p. 171. ‡ See *ante*, p. 172.

We have confined our attention to one sheet or plate of glass only; and before proceeding further, we may observe, that the thickness of the glass has a decided effect on the readiness with which the two sides may be polarised. This arises from two causes—namely, the distance between the sides, and the partial polarisation which the material itself undergoes. It is therefore essential, in making a Leyden jar or battery, that the glass employed should be as thin as possible, as on that depend both the facility of charging and discharging the arrangement.

We shall now examine the effect produced on a number of particles, with respect to the electrical arrangement which they assume when in an excited state; and we shall represent the quiescent and active condition by means of a diagram, which will assist in conveying the subject in an intelligible manner to our readers. For this purpose, we shall suppose the following arrangement to represent the twofold state to which we have alluded. Of course, we do not intend to assume that the particles we speak of are those of electricity. We presume that they are the atoms of a body, in which electricity is respectively in a latent and active form.

No. 1. NP NP NP NP

No. 2. N PN PN PN P

We here suppose the existence of four atoms of a body, whose sides are respectively negative and positive; but in No. 1, such states are those of *latent* or combined electricity. If, however, by means of the electrical machine, we induce an *active* state, then the previous electrical equilibrium is at once disturbed; and, as we observe in No. 2, the electricities arrange themselves so that at each end of the series of atoms we have a free electricity; and, intermediately, the electricity of one atom instantly acts on, and induces action on, that of its neighbour. If a connection be made between the opposite electrical states, at the extremities of the series of excited atoms, then they are at once restored to the condition shown in No. 1, and the equilibrium is thereby reproduced.

It will thus be perceived, that electrical induction takes place when an excited body is brought near to one in a quiescent state; that the effect produced is that of arranging the electricities of the previously unexcited body in a polar state; and these laws hold good, no matter how many particles may be affected, provided that the exciting power is of sufficient energy.

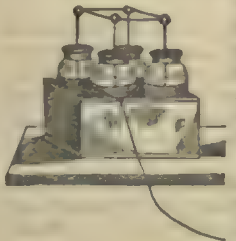
It will be presumed, in all future experiments, that our readers will bear these facts in mind, and that when we speak of induction, they will fully understand the term in all its bearings.

We shall next proceed to illustrate the various effects which a powerful charge of electricity, as afforded by means of the Leyden battery, produces; and shall divide these into mechanical, luminous, calorific, and physiological phenomena; although, occasionally, two or more of these classes are simultaneously produced by the same experiment.

THE MECHANICAL, LUMINOUS, AND OTHER EFFECTS OF ELECTRICITY.

We shall now suggest numerous experiments which can be tried by the Leyden jars or battery, in which the various effects of a powerful charge of electricity will be exhibited; and shall also examine some natural phenomena in which that force is the active agent.

Fig. 26.

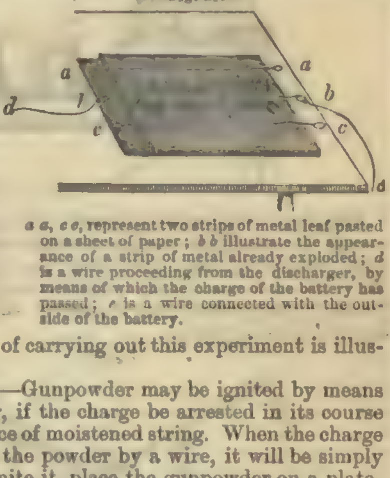


Most of the experiments we shall introduce, may be tried by means of a plate machine of from twelve to eighteen inches in diameter in the glass plate, and with a battery of from two to four jars. To facilitate the construction of an arrangement of the kind, we refer to Fig. 26, which represents a battery of four jars, of about three pints capacity each. Such is sufficient for a vast variety of experiments, and each jar may be of the simple kind we have already described.*

The different parts of this Leyden battery correspond in every respect, except as to size, with that illustrated at a previous page.† Before commencing any experiment with the battery, care should be taken that the outside of the jars be connected with some good conductor, such as a gas, drain, or water-pipe, as on that will depend much of the success which may be desired. As it is impossible to separate the mechanical, luminous, and calorific effects of frictional electricity, we shall introduce our experiments without reference to such distinctions; pointing out, however, as we proceed, any notable matter which may arise.

Experiment 23.—*Combustion of Metal Leaves.*—For this purpose, a narrow strip of gold or silver leaf is to be pasted on paper. The width of the strip of metal, as well as the length, depends on the power of the battery; but a strip of an eighth of an inch wide, and eight inches long, may be used. The paper should be well dried; and strips of several metals may be then pasted on it. The paper so covered is to be fastened on to a well-dried board, and one end of the metal strip is to be attached, by means of a wire, with the outside of the battery. The other end of the strip may be connected with the knob of the discharger at *a*—illustrated already.‡ To the other knob, marked *f*, the inside of the battery must be attached by a wire. By such means the charge will spontaneously discharge itself. In the absence of such an arrangement, the ordinary discharger may be used, one of its ends being brought into contact with the inside of the battery by means of a wire; and its other end, after the battery is charged, is to be brought in contact with the strip of metal. On the charge being thus directed over the metal strip, a loud explosion will take place, and the metal foil will be destroyed. The effect on the paper is often very pretty, owing to the dispersion and oxydation of the metal in all directions. The mode of carrying out this experiment is illustrated in Fig. 27.

Fig. 27.



a a, *c c*, represent two strips of metal leaf pasted on a sheet of paper; *b b* illustrate the appearance of a strip of metal already exploded; *d* is a wire proceeding from the discharger, by means of which the charge of the battery has passed; *e* is a wire connected with the outside of the battery.

Experiment 24.—Gunpowder may be ignited by means of the Leyden jar, if the charge be arrested in its course by means of a piece of moistened string. When the charge is sent directly to the powder by a wire, it will be simply dispersed. To ignite it, place the gunpowder on a plate, and dip into it a wire proceeding from the outside of two jars. Attach a piece of wet string to one knob of the discharger, and to the end of the string fix a piece of wire, which is to rest on the gunpowder, at a short distance from the end of the wire proceeding from the outside of the jars. When they are fully charged, bring the other knob of the discharger into contact with their inside coatings in the usual manner, and the powder will be at once ignited. Fig. 28 shows the proper method of conducting the experiment.

Experiment 25.—Two very singular effects may be produced by causing the Leyden discharge to pass between two plates of glass. A narrow strip of gold leaf is to be placed between two slips of common window-glass, which may be an inch wide and four inches long. These should be tied tightly together, and the metal leaf should extend about half an inch beyond each end. One end of the leaf is to be attached to the outside of the battery, and the plates should be insulated by placing them on two glasses.

---

* See *ante*, p. 180. † *Ante*, p. 179. ‡ *Ante*, p. 180; Fig. 23.

When the battery is charged, it is to be discharged by means of the usual discharger; and the mechanical effect will be such that portions of the gold leaf will be driven into the glass, and the two plates shivered into numerous small pieces. This experiment requires great care, as the broken pieces are exceedingly sharp, and fly to a considerable distance on all sides. It is advisable that a kind of screen be placed over them, to prevent accident to the experimenter. The following engraving illustrates the whole arrangement.

Fig. 28.

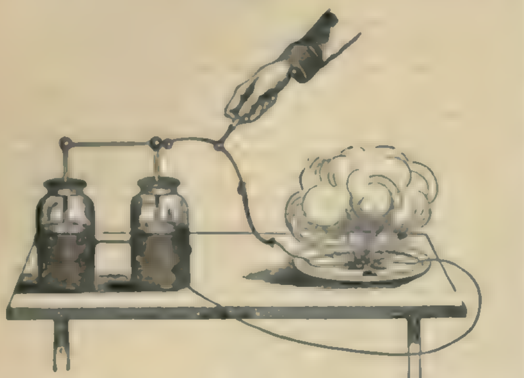


Fig. 29.

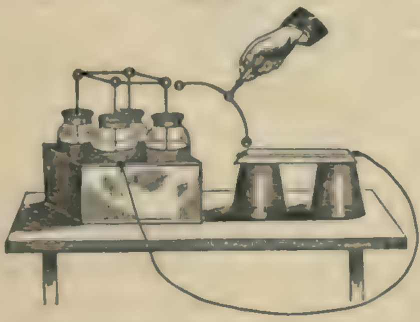
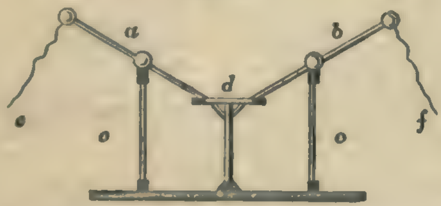


We have frequently shivered into almost dust, by means of the hydro-electric machine and twelve large jars, pieces of glass a foot long and four inches wide. For this and many other similar experiments, a convenient arrangement may be made, which is illustrated in the following figure.

Fig. 30.



In the engraving, *a b* are two brass rods, which are easily moved on universal joints, secured to two glass pillars, *c c*; *d* is a small table, on which the object to be experimented on is to be placed; *e* and *f* are two wires for conducting the electricity from the battery. One of these is to be attached to the outside of the battery, and the other to the discharging rod, so that when the battery is charged, the electricity may be thereby conveyed to the table of the apparatus. We shall suppose that the student will supply himself with an arrangement of this kind, which, in fact, he can easily construct, in a rough way, himself; and which he will find a matter of great convenience. We shall in future call it the "universal discharger." We may add, that a similar arrangement will be required for many experiments in voltaic electricity. In the engraving, we have represented the ends of the discharger as terminating in points; two brass balls will, however, be occasionally required in some of the experiments.

Experiment 26.—Place a few sheets of paper between the two points of the universal discharger, and pass a charge through them. The mechanical effect will be so great as to perforate them with ease.

Experiment 27.—Place a piece of loaf-sugar on the table, and bring the ends of the discharging rod in contact with it on its opposite sides. The charge will pass through the sugar if the points be closely pressed on it, and it will be shivered into pieces. A beautiful phosphorescence will be noticed if the experiment be tried in the dark. A piece of dry wood, if similarly placed, may easily be broken to pieces.

Experiment 28.—Cork tightly one end of a narrow glass tube, and insert a wire in the cork, so that its two ends may be respectively inside and outside; and having filled the tube with distilled water, cork up the other end, with a wire also inserted in the cork, and let the two wires be separated to a short distance in the tube from each other. Place this on the table of the discharger, and bring the two rods in contact with the two wires of the tube. If a charge from the battery be now effected, the tube will be burst into pieces, owing partly to the mechanical expansion of the liquid, the effects of the heat generated, and the partial decomposition which the water undergoes. We annex an engraving, which will assist the student in carrying out the experiment. (See Fig. 31).

Fig. 31.

We must here warn our readers, that care should be taken lest the pieces of glass be driven into the face of the experimenter: a small iron cage placed over the tube is a prudent precaution.

Experiment 29.—A very pretty luminous effect is produced by sending the battery charge through a piece of alum. This is best done by boring a hole on each side of the salt, so that when the points of the rod of the discharger are inserted, they may be at a distance of a quarter of an inch from each other. On the discharge being effected, the alum will become beautifully illuminated, and be broken to pieces.

In the preceding experiments we have chiefly observed the mechanical and luminous effects of frictional electricity; we will, therefore, give some instances in which the calorific effects of the force are manifested.

Experiment 30.—Connect the two rods of the universal discharger by means of a very fine piece of steel wire, about six or eight inches in length, and send the charge of the battery through it. The wire will be instantly melted, and will fall down in fine globules. Steel and other metallic wires may be thus melted. This result may be obtained by a single Leyden jar, if of about three pints capacity: the wire is to be attached to one knob of the common discharger, and so may be brought into contact with that of the inside of the jar; the other knob of the discharger must rest against the outside of the Leyden jar.

Experiment 31.—A gas-lamp, or newly-blown-out candle, may easily be ignited by means of the battery. The ordinary discharger must have one knob in contact with one belonging to the jars of the battery, and the other knob is to be brought nearly into contact with the gas jet. A wire should stretch from the metal pipe to the outside of the battery.

These experiments will be sufficient to illustrate some of the mechanical and other effects of a powerful electric charge. We shall now proceed to put our remarks to a practical purpose, by referring to the use of lightning conductors in protecting tall buildings, chimneys, steeples, masts, &c.

ATMOSPHERIC ELECTRICITY—LIGHTNING CONDUCTORS—THE ELECTRIC KITE, Etc.

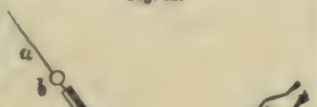
There are, perhaps, none of our readers who are not familiar with the destructive results which are occasioned by severe thunder-storms; and we shall now enter into some examination of the phenomena of atmospheric electricity, and explain the inventions of various kinds which have been brought out for the purpose of averting the danger arising from an over-accumulation of electricity in the air.

Franklin was the first to discover that atmospheric and frictional electricity are identical in all respects. He was also the first "to draw fire from the clouds;" except we give that honour to Prometheus, whom some have considered to have been the earliest inventor of lightning conductors. Franklin, for the purpose of ascertaining the presence of electricity in the air, raised a small kite; having chosen, for that purpose, a day when a thunder-storm was expected. For some little time no success attended his experiment; but when the string became wet, and so was a better conductor, he was enabled to draw sparks from it by means of a key, and so solved at once the problems of atmospheric electrical disturbances. Perhaps some of our readers may be desirous of repeating Franklin's experiment; and it will, therefore, be as well for us to give a little advice on the subject, and so to diminish the chance of danger which always arises in such attempts.

A kite, from four to six feet long, may be employed; and, at the top, a sharp metal wire should project about two inches. This wire is to be connected with the long string by which the kite is to be flown. This string should have a fine copper wire twisted inside the external hemp, which is easily done; and, of course, highly improves its conducting power.

Great care is to be observed in flying the kite. After raising it a short distance, a dry silk handkerchief should be slipped round the string, noose-fashion, and the extreme end of the string may be fastened round a tree. The kite is raised by holding the string by means of the silk handkerchief, so that the former may readily pass through it. Of course, the object of the silk is to act as a non-conductor, and so to prevent the passage of the electricity to the body of the person holding it. The elevation of the kite may be from 200 to 1,000 feet. The portion of the cord wound round the tree may be loosed when the kite is sufficiently elevated, and its end is to be attached to the silk handkerchief, and it will be ready for experimenting with. It is well to have the rod on which the string is wound made of copper, with a ring at each end. By means of this ring and the silk handkerchief, the string may be fastened to a well-dried stick thrust into the ground, as shown in the above figure; and so the conducting link will be broken with the earth, and sparks may be obtained from the metal rod. In Fig. 32, *a* is the metallic string proceeding from the kite, and fastened on the ring *b*; *c* is the metal rod; *d* is the ring to which the silk handkerchief, *e*, is attached; *f* is the ring of a post of dried wood, fixed in the ground; *g* is a discharger, the glass handle of which should be at least two feet long; and *h* is a wire conducting the electricity from *d* to the ground.

Fig. 32.

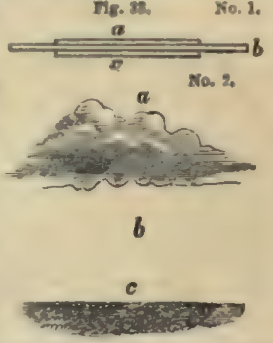


The kite experiment should never be tried during stormy or hazy weather, because such would most likely prove highly dangerous. Fatal accidents, indeed, have occurred from want of caution; and we should not have given directions for carrying out the trial, except under the idea that some of our readers might resolve to attempt it for themselves, and, in the absence of proper precautions, might have sustained injury. We have frequently adopted the plan we have described, and therefore recommend it with confidence. It is, however, advisable that no tyro should ever attempt to fly the kite under any circumstances.

The most celebrated electrical experiments of this kind, of modern times, are those which were conducted by Mr. Crosse, of Bromfield, near Taunton, who was a complete devotee to electrical science. This gentleman erected, on ground near his house, a large number of metallic rods, which were insulated at their lower end, and joined together by a rod, the terminal of which entered a room specially arranged for electrical experiments. Opposite to the terminal was placed a rod of metal, which, by sliding to and fro, could be fixed at any required distance from the rod communicating with the external conductors. By these means he was able to conduct a thunder-storm and its effects into a small space, and the results he obtained were of the most extraordinary character. During stormy or hazy weather, brilliant flashes of light were observed between the conductors, accompanied with terrific crashes of sound, and violent reports. The entire effects were sometimes quite appalling, and cannot be conceived by any one who has not seen them.

Now, it is plain, from these experiments and results, that, by means of proper arrangements, electricity may be conducted (to use an ordinary phrase) from the clouds. But we must now be more philosophical in our remarks, and explain the phenomena of thunder-storms, &c., in accordance with the principles already laid down. In doing this, we shall materially assist the student in understanding the circumstances which attend the development of atmospheric electricity, by comparing the arrangement of the Leyden jar, or piece of flat-coated plate, with that of the clouds, air, and earth. We shall consider, therefore, that the air corresponds to the glass of the jar, the clouds to its inside, and the earth to its outside coating. Lightning conductors we shall hold in the light of a discharger, such as is usually employed in our experiments. This may be better understood by the illustration which the annexed engraving affords.

Fig. 33.



In Fig. 33, No. 1, we have a piece of window-glass, *b*, coated at *a* and *c* with tinfoil. Now, we have already shown, that if *a* or *c* be positively charged, the opposite will become negatively so by induction. Similarly, in No. 2, we shall suppose the clouds, *a*, to be charged positively; the air, *b*, which corresponds to the glass, *b*, in No. 1, to be intermediate between the clouds and the earth; and the earth, *c*, by induction, will necessarily be in a negative state.

In a former page,* we have stated, that when a jar is overcharged, it will generally discharge itself; and this is exactly what occurs in nature. The high charge of the clouds is spontaneously discharged to the earth; and just as we have the spark and snap of the jar, so, in the large scale in nature, we have the flash of lightning and the clap of thunder. It will thus be seen that the analogy is complete.

We may, however, go a step further, and remind our readers, that if a wire be stretched from *a* to *c* (No. 1) whilst the former is charged, the discharge takes place without any external manifestation. In the very same way if a tall metallic rod be raised from the ground, *c*, towards the clouds, *a* (No. 2), a silent discharge at once takes place; and this is precisely the way in which lightning conductors act. The common notion is, that lightning conductors *attract* the lightning—an idea which is entirely erroneous. They simply form the readiest and most effectual means of restoring the electric equilibrium of the earth and clouds, and only so far are they of any use or purpose.

---

* See *ante*, p. 179.

We may briefly glance at some practical matters in connection with this subject, which may be useful to any of our readers desirous of putting our remarks into active use.

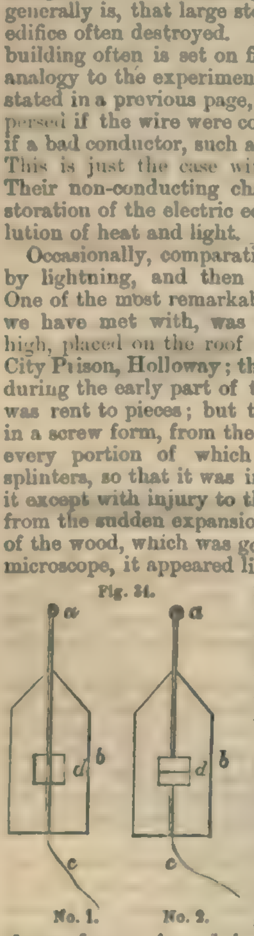
The conductor should have its upper end pointed, for reasons previously explained.* Its lower end should be not less than from three to four feet imbedded in the earth, for the same reason that we connect the outside of a battery with a gas or water-pipe.† Copper, being a better conductor than iron, is to be preferred; but galvanised iron answers very well.

All the adjacent metallic objects, such as the leaden or zinc roof of a house, should be connected with the conductor, because they might possibly act in independence of it, and produce antagonistic results. The top of the rod should extend much beyond the highest part of the building, and should not be attached to the chimneys of private houses, because the fine soot they contain is, to some extent, a conductor.

In many large buildings, such as churches, the stones of the steeple, &c., are tied together by means of iron clamps. In the absence of a conductor, these produce the most serious results in a storm. The weathercock is first struck as the most prominent metallic object, and then every metallic tie in the building succeeds as a conductor. These being at a distance from each other, do not permit of a continuity of conduction; and the result generally is, that large stones are thrown down, and the edifice often destroyed. Under such circumstances, the building often is set on fire; and here we have an exact analogy to the experiment of igniting gunpowder. We stated in a previous page,‡ that the powder would be dispersed if the wire were continuous, but would be ignited if a bad conductor, such as a wet string, were interposed. This is just the case with the stones of the building. Their non-conducting character prevents the rapid restoration of the electric equilibrium; and hence the evolution of heat and light.

Occasionally, comparatively bad conductors are struck by lightning, and then destruction is sure to follow. One of the most remarkable instances of this kind which we have met with, was that of a flag-staff, forty feet high, placed on the roof of a large inn opposite to the City Prison, Holloway; the destruction of which occurred during the early part of the summer of 1861. The staff was rent to pieces; but the course of the lightning was in a screw form, from the top to the bottom of the wood, every portion of which was divided into the finest splinters, so that it was impossible to touch any piece of it except with injury to the hand. This seemed to arise from the sudden expansion of the moisture in the fibres of the wood, which was good pine. When viewed by the microscope, it appeared like a bundle of fine hemp fibres rather than solid wood. At the time of the occurrence, the entire house seemed filled with flame, but no further damage was effected. A strong sulphurous smell was noticed for some time afterwards.

Fig. 34.



An experimental illustration of the effect of non-conductors, or of breaks in the conductor, may be made by the arrangement represented in the annexed engraving.

In the cut, the same letters are used for each figure. *a* is a brass knob for receiving the charge from a jar; *b* is a piece of dried wood, in the shape of the gable of a house; *c* is a wire conducting to the earth; and *d* is a small square of wood, with tinfoil pasted on it, and movable in the larger frame. Now, in No. 1, the conductor is continuous from *a* to *c*, and so the piece of wood, *d*, would not be disturbed by a charge. But if a jar be discharged on No. 2, then the wood, *d*, will be rapidly ejected from its place, because the conducting course is broken by its position and that of the tinfoil being changed.

Trees being moderately good conductors, are often similarly injured; but unless they are very dry, they are not, generally speaking, cloven into pieces. The rain which usually falls in a thunder-storm, improves the conducting power, and so renders them exceedingly dangerous as places of shelter for man or animals. A singular circumstance came under our notice, three years ago, at Glasgow. Three persons had taken shelter under a tree, which was subsequently struck with lightning. They were all prostrated and rendered insensible for a time, from which they soon recovered; but, singular to say, the heels of their boots were completely torn off, owing to the conducting power of the nails in them. This is another illustration of the remarks we have just made, in reference to the necessity of continuous conductors from the different metallic arrangements in buildings.

It seems a tolerably well ascertained fact, that persons struck by lightning fatally, undergo rapid decomposition. The cause of this is by no means evident: it is stated, however, in such instances, that the albumen of the blood does not coagulate, as is usual in ordinary cases of death.

When injury by lightning has taken place, it is well to treat the person in the same manner as would be adopted for drowning; the object being to restore, as speedily as possible, suspended animation. The latter is caused by a cessation of the action of the heart, and consequent asphyxia. Occasionally the application of electricity may be tried when the means of doing so are within reach; and, on breathing and feeling being restored, recourse should at once be had to the warm bath, and subsequent rubbing with very coarse towels.

Before quitting the subject of thunder-storms, we may make a few observations on the cause of the rolling sound of thunder. This is entirely owing to the echo produced by the clouds overhead. The noise of the discharge would, like that of the Leyden jar, be single were it not for this cause. On a cloudy day, if the report produced by the discharge of cannon be noticed, a precisely similar effect is produced, and successive, instead of single sounds, are heard.

Another atmospheric phenomenon, most commonly observed in the northern regions, is the aurora borealis, the cause of which we ascribe to a discharge of electricity in a highly rarefied medium. We have already given an experiment illustrating its appearance in a previous page,§ and shall not further enter into the subject here, as it more properly belongs to the department of meteorology.

PHYSIOLOGICAL EFFECTS, AND ANIMAL ELECTRICITY.

UNDER the above heading we shall include some of the physiological effects of electricity, together with a short account of fishes, which have the power of transmitting electric shocks from their bodies. We shall have to extend considerably on this subject in our next chapter: we shall therefore here confine our remarks to those effects which are due to electricity excited by friction, or its analogues.

Physiological Effects.—If the knuckle be presented to the conductor of an electrical machine, a tingling sensation will be experienced as the spark passes. If, however, one hand be placed on the knob of a charged jar, whilst the other grasps its external coating, a powerful shock will be felt; which will possibly, if from a pint jar, extend as far as the chest. This effect is produced by the sudden and powerful contraction of the muscles. Any number of persons may readily take a shock simultaneously (if the jar be large enough), by joining hands, and by the last person at each end respectively touching, one the knob of the inside, and the other the outer coating of a charged jar. A convenient way of doing this, is illustrated in the following engraving.

---

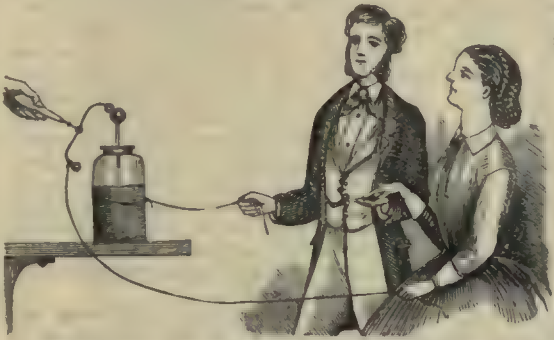
* See *ante*, p. 175.

† *Ante*, p. 179.

‡ *Ante*, p. 181.

§ See *ante*, p. 173; Fig. 6.

Fig. 35.



By this mode, one person holds a wire proceeding from the outside coating of the jar: the last person in the series, holds the wire which is attached to the discharger; and an assistant connects it with the knob of the charged jar, and so gives the shock.

Individuals vary much with respect to their susceptibility of electric shocks. If several persons take a shock together, those having a moist skin on the hands will feel it most acutely. If, however, a shock be taken so that it may pass over the whole body, then the moisture on the skin diminishes the pain by making the body a better conductor. Persons with a harsh, dry skin, feel a shock, with a number of persons, less than they do when taking it singly; and owing to this, a few persons having a dry skin, placed amongst others, will retard and diminish the effect on those with whom they may be joined by the hands. For that reason, the hands are sometimes wetted to improve the conducting power. We have frequently taken, whilst in a violent perspiration, with impunity, a two-inch spark from the hydro-electric; and have also been amused at others, whose skin was entirely dry, calling out, in severe pain, with a shock of the same intensity, which they were induced to try from observing its trifling effect on ourselves.

Considerable care should be observed in giving an electric shock, in any form, to females and young children, as one too severe might be productive of serious injury, in consequence of its effect on the nervous system. A half-pint charged jar is quite large enough for one person; whilst one from a quart to three pints capacity, will give a strong shock to twenty or more persons joining hands together.

Electricity, in the shape of sparks, was, at one time, in high favour in medical circles, for relieving acute pain in neuralgia and nervous complaints generally; and, at its first application, like all other novelties, it was held out as a panacea for "all the ills that flesh is heir to." In the present day, the coil machine (which we shall describe in a future page) is chiefly employed for that purpose, because it is easily set into action, and the strength of the shock, which may be continued for any length of time, is entirely under control.

There is no doubt that electricity, in animal bodies, is an active agent in sustaining life. The nerves and the muscles are not only affected thereby, but always exhibit a current of electricity if proper means be employed to detect it. This is a subject, however, on which we shall have to expand hereafter, as it more particularly belongs to that of voltaic electricity.

Electrical Fishes.—Some animals can set free from their bodies, spontaneously, a large amount of electricity: amongst these are the *torpedo*, the *gymnotus electricus*, and the *silurus electricus*.

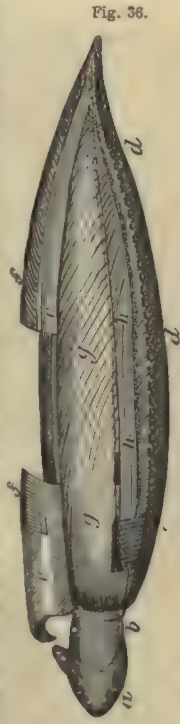
Each of these fishes has the power of giving an electric shock. The *torpedo* is a native of Europe; and its electric organs are placed in its body in a manner which is analogous to the arrangement of a Leyden jar; for the shock is obtained by placing one hand on the belly, and the other on the back of the fish.

The *gymnotus* is a fish of the eel kind, and is chiefly found in the rivers of South America. It has a very powerful effect on other animals, and can not only stun them, but even destroy life by its shock. One of these was exhibited, some years ago, at the London Polytechnic. It was about three feet long, and was kept in a circular tank of water. Two wires were laid inside; and these extended to the outside of the tank, and ended in two basins of water. If the hands were dipped in the basins, a powerful shock was experienced, about equal to that of a fully-charged half-pint Leyden jar. The strength of the shock varied, however, from day to day, according to the activity of the fish.

The *silurus electricus* is a native of Africa, and is an inhabitant of swamps, &c. Its shock is similar to that of the Gymnotus, but its natural history is not so well known.

In the annexed engraving, a representation of the various internal organs of the *gymnotus electricus* will be observed.

Fig. 36.



In the above, *a* represents the head; *b*, the cavity of the body; *d d*, the ventral fin; *e e*, the skin; *f f*, the muscles of the fin; *g g*, the electrical organ; and *h h*, the smaller organ.

CHEMICAL EFFECTS.

The chemical effects produced by frictional electricity are so feeble as to be scarce worthy of notice, were it not that they complete a chain of analogy with similar results produced on a much larger scale by other modes of developing the electric force. This is owing to the fact, that electricity obtained by friction, has great intensity or power of overcoming obstacles presented by bad conductors, such as the air, &c.; but has little or no quantity, or that which would tend to act on a large surface or mass energetically. A few plates of zinc and copper, arranged as a voltaic battery, rapidly decompose water which has been rendered a better conductor by the addition of some sulphuric acid; whereas, pure water, which would scarcely be acted on by voltaic electricity, must be employed for the purpose of decomposition by electricity obtained by friction.

The mode usually adopted for this end, is that of employing two gold wires, the extreme points of which are alone exposed to the liquid. A continuous current from a large plate machine, the conductor of which is connected with one wire, may be used; the other gold wire is to be connected with the earth; and so a continued current passes between the points of the wires, which should be near to each other. Minute bubbles of gas will be seen to rise, which are those of oxygen and hydrogen. The process is extremely slow, difficult of pursuit, and requires care in the entire arrangement. Minute quantities of metallic solutions, such as of sulphate of copper, have been decomposed by the action of the hydro-electric machine, which was evidenced by the deposition of metallic copper on one of the wires. Feeble, but decided evidence has been adduced, that the *gymnotus electricus* has the power of decomposing water—a result which, we believe, was first obtained by Dr. Faraday. This fact goes to prove the identity of the electricity obtained from the fish, with that produced by friction.

CHAPTER II.

VOLTAIC ELECTRICITY

It may, perhaps, be no exaggeration to say, that scarcely any branch of experimental science has produced so great a social revolution as that which we are about to investigate. Within the short space of some sixty or seventy years, that which was, comparatively speaking, a philosophic toy, has become the cement of national, social, and commercial relations. The simple experiment which, according to the generally received opinion, first gave birth to the idea that electricity could be set free by chemical action, has expanded to an extent far exceeding the most sanguine hopes of its discoverers, and has become, in its applications, a positive necessity of daily life.

Most of the remarks and experiments we have given in connection with frictional electricity, have a decided bearing on the subject with which we now have to deal. Indeed, we shall presume that the student and general reader has entirely mastered all the laws and phenomena (so far as the present state of our knowledge will permit) to which reference has already been made. Even the terms and expressions we have employed will have to be constantly repeated in our future pages, and, as such, they will form the groundwork of further progress.

The history of voltaic electricity, or, as it is sometimes termed, galvanism, is connected with the early researches of two Italian philosophers. It is stated, that Galvani first noticed how the contact of a metal with the nerves of the leg of a frog, produced muscular contractions in the limb; and that Volta, extending the idea, found that the "contact of two metals" was sufficient to produce various electric phenomena. We have hitherto carefully abstained from entering into any discussion as to the relative merits of individual discoverers or inventors. The natural pride and conceit of humanity is always prostituting to its own purposes the novelties of scientific research which are continually arising; and we can refer to no fact more degrading to the dignity of human intelligence, than that its chief possessors have, from the days of Newton and Leibnitz, been found engaging in personal disputes as to the priority of discovery, where humility of mind and a pure love of science ought to have been the reigning principle. Unfortunately, it is too true, that to err is human; and yet we may, and ought not to be too Utopian in our hopes, if we predict that the day will arrive when the consciousness of having extended the limits of our knowledge, and of having been the instruments of benefiting our fellow-creatures, shall be the highest reward to which "philosophers" can aim at.

It is useless for us to describe the contests which took place, many years ago, between those who maintained the theory of contact, and others who advocated the idea of chemical action, as the cause of the development of voltaic electricity. The former imagined that the mere contact of two dissimilar metals was the sole exciting cause. Dr. Faraday, however, by a series of masterly researches, proved, that on such contact taking place, chemical action instantly ensued; and, further, that electricity was evolved by chemical action in circumstances where contact was impossible. We may add, that just in proportion to the chemical action in a voltaic battery, so the quantity of electricity set free is increased; and, at the present time, we are not aware that any advocates of the contact theory are to be found. We shall at once proceed with our subject, and commence our experiments with voltaic batteries.

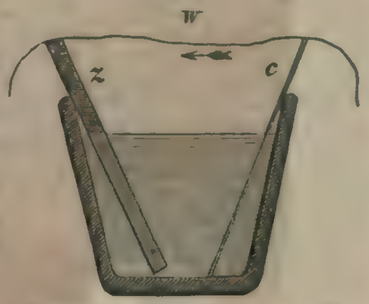
VOLTAIC BATTERIES.

It is an unfortunate circumstance, that many of the terms employed in science do not sufficiently indicate the meaning and object they are intended to express; and hence the beginner incessantly finds obstacles to his progress. An amusing illustration of the ignorance of even well-educated persons, with respect to this point, came under our notice whilst effecting a fire insurance some years ago. The agent of an office gravely objected to the presence of voltaic batteries on the premises; expressing an opinion that they were highly dangerous, and enforcing his views by stating that they never issued a policy when *gunpowder* was kept in a building. He had confounded the term *battery* with its military signification, and was utterly surprised to see fifty cells of Grove's "batteries," "charged" with acid and water, instead of the *matériel* of warfare.

A voltaic battery is a combination of cells, each containing the materials requisite to the production of electricity by chemical action; and we shall now proceed to examine such arrangements theoretically and practically.

If a piece of zinc and a silver coin are placed on either side of the tongue, no sensation of any sort is experienced until they come in contact in some part: but on that taking place, a peculiar metallic taste is perceived in the mouth. The elements of a voltaic battery are employed in this experiment. A current of electricity is excited by the action of the moisture of the tongue on the zinc; and it passes from the zinc, through the liquid to the silver, at their point of junction, and so back to the zinc again.

Fig. 37.

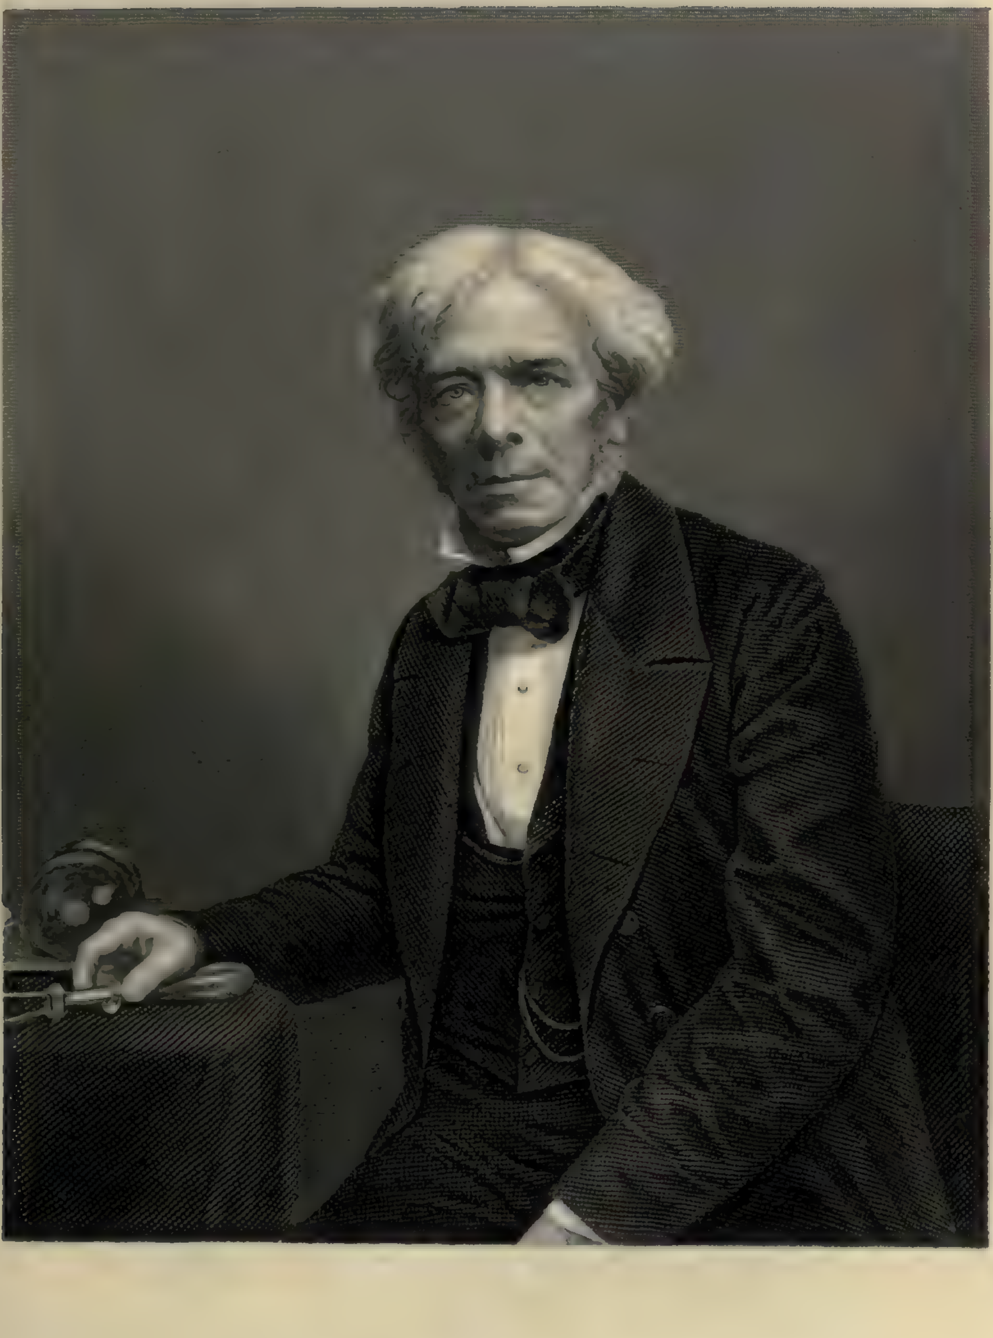


A more satisfactory mode of illustrating this interesting fact, is represented in the annexed engraving.

Experiment 32.—Place a sheet of zinc which has been cleaned in a little sulphuric acid and water, and rubbed over with mercury till it is quite bright, in a glass vessel, and opposite to it a sheet of copper, so that they do not touch. The glass is then to be nearly filled with a mixture of one part of sulphuric acid to eight parts of water. No action of any sort will be perceived. But if a wire be placed across both plates, as represented in Fig. 37, so that it may join the two, then a current of electricity will pass from the zinc plate, *z*, through the liquid to the copper plate, *c*, and, passing by the wire, *w*, in the direction indicated by the arrow, it will at last return to the zinc plate; abundance of hydrogen will be given off from the copper plate. If the wire be broken in any part, and its extremities be kept in contact with each plate, the tongue will feel the same sensation when in contact with the ends of the wire, as that which we have already alluded to; and thus the existence and passage of an electric current will be at once made evident to the senses. Each of the plates of the battery is named in accordance with the theories we have already discussed in the last chapter.[*] The zinc plate is called the positive, and the copper the negative, element of the battery; and we may here lay down, as a general rule, that that metal which is most acted upon in a voltaic battery, is positive to the other metal.

---

[*] See *ante*, p. 178.



MICHAEL FARADAY, ESQ., F.R.S., D.C.L.

[illegible]

There are several circumstances into which we shall here inquire, which modify, increase, or diminish the power of voltaic batteries. They may be shortly summed up as follows :—

1. The extent and rapidity of chemical action.
2. The size of the plates.
3. The conducting power of the liquid used as an excitant; and of the wire, &c., joining the plates, external to the cell.

We have already mentioned, that there have been those who have strongly advocated the idea, that the production of electricity by the voltaic battery, is due to the contact of dissimilar metals. The causes of the modification of the power of the voltaic battery, which we have given above, recognise no such an opinion. Indeed, it is not necessary that we should bring into contact the two metals at all; for in all chemical decompositions affected by voltaic electricity, the metals are never connected by a wire—as shown in Fig. 37;* but merely by the liquid which is the subject of the electric action.

1. That the power of a cell depends on the rapidity of the chemical action which proceeds on one of the metals, is made evident by the following experiment :—

Experiment 33.—Connect a piece of zinc and copper plate, each four inches square, by means of a very fine piece of steel wire. This is best done by soldering a thick copper wire to each plate, round which the steel wire is to be twisted, so as to leave about half an inch of the fine wire between them. Dip the plates into common water, and no effect will be perceived on the fine wire. Now replace the water by strong sulphuric acid, diluted with six times its bulk of water, and introduce the plate into it. The steel wire between the two copper wires will be instantly melted.

2. The size of the plates has the effect of increasing the power of a cell, in respect to the quantity of electricity which is set free. Thus, in the last experiment, a very thin wire was recommended, because the plates were small. If, however, large plates be employed, then just in proportion to the extent of the surface of the plates, so will greater thicknesses of wire of the same kind be melted. It is hence usual to adjust the size of all voltaic batteries to the work which they are expected to perform. This will be particularly noticed when we have to refer to the chemical decomposition, &c., carried on during the electrotype process.

3. The conducting power of the liquid in each cell, and that of the wire, &c., external to it, are matters of the highest importance. Liquids, in an electrical point of view, are, generally speaking, bad conductors; but, in a voltaic battery, this fact is modified by means of mixing acids, &c., with the water used as an excitant. Pure water has so little chemical action on zinc, and is so bad a conductor, as to afford only the most feeble evidences of disturbing electricity; whereas, if a little acid be added thereto, the result is, that rapid chemical action may be speedily induced. The conducting power of a liquid is inversely as its length; hence it is essential that the two plates of a cell should be placed as near as possible to each other without touching. As an illustration of this, we may state, that twelve sets of copper and zinc plates, each at a distance of an inch from each other, do not afford a tenth part so much effect as when they are so arranged as to be in as close proximity as possible without touching. The addition of sulphuric, nitric, and hydrochloric acids, of salts, &c., to the water of a cell, increases its conducting power almost in proportion to the extent of their presence; hence strong solutions of the above are always employed when brilliant effects are desired from voltaic batteries. The wires forming the terminals of a battery or single cell, always, like the liquid in the cell, afford a resistance to the passage of electricity; and this depends on their thickness and length. Different metals vary in their conducting power—gold, silver, and copper standing the highest, and lead, tin, zinc, &c., lowest in the scale. For all practical purposes, copper wire is employed as a conductor in all voltaic batteries; and we suggest the use of flat ribbons of the metal in place of wire, as being more convenient where long conductors have to be arranged.

A voltaic battery consists simply of a number of single cells joined together. The zinc of one cell is attached, by means of a wire, to the copper of the next; and so on, throughout the series. By this arrangement, one zinc and one copper, at the extreme ends of the battery, will be unconnected; and it is to these that the terminal wires, by means of which the experiments are carried on, are attached.

The *intensity*, or power of a battery to overcome resistance offered by bad conductors, such as air and water, depends on the *number* of cells employed.

The *quantity*, or power to overcome the resistance of good conductors, such as metallic wires, in melting them, depends on the *size* of the plates. On the regulation of these two particulars in the construction of voltaic arrangements, their efficiency for all purposes is governed. It may be well that we should here give some general directions as to the management of voltaic batteries generally, before proceeding to describe the various kinds which have been invented. And first, the zinc should always be amalgamated. This prevents the acid acting on the metal, except when the battery is in action; and it is easily performed. The zinc plate should be dipped into some strong sulphuric acid and water, until abundance of gas arises from its surface. It may then be laid on a plate, and mercury is to be rubbed over it until the whole presents a highly polished appearance on both sides. If the metal be now dipped again into the acid water, no gas will arise from its surface, because the mercury has covered over a vast number of impurities, consisting of iron, &c., which are in the zinc, and which formed little batteries on its surface. This process has been of the utmost importance in the application of voltaic batteries; and diminishes to a great extent their working cost, by economising the zinc.

Every junction of metals, wires, binding-screws, &c., should be kept quite bright; and, wherever possible, soldering should be employed, as complete contact of all connecting arrangements is very essential. We have seen batteries in a dirty condition which would scarcely melt an inch of wire; and yet, with the same charge, they would melt five or six feet, after all the connections were carefully cleaned. For this purpose common sand-paper should be used, or sand may be rubbed on to the metals, by means of a damp cloth, until they are quite polished. In winter-time the action of a battery will quite cease, if the weather be very cold. Of course, the only remedy is, to carry on the experiments in a warm room, or to heat the solutions before charging the battery.

In using those batteries having porous cells and two liquids (Daniell's and Grove's), great care should be taken not to allow the two liquids to mix, as this would ruin the zinc: and the porous cells, when done with, should be completely emptied, and left to soak in water, so as to remove all salts, which would crystallise and break them to pieces.

It will occasionally happen, in large batteries, that the middle cells will get very hot, and the liquid will evaporate from them. This of course must be watched, and, if necessary, they must be refilled. The student should bear in mind, that the power of the battery is regulated by the action of the *feeblest* cell of the whole series. It is therefore essential that each should have the same charge, equal-sized plates, and that the connection should be perfect throughout. After using wires for voltaic experiments, they sometimes become completely rotten, and break with the least touch. This is remedied by heating them red-hot, which at once softens them.

DIFFERENT FORMS OF VOLTAIC BATTERIES

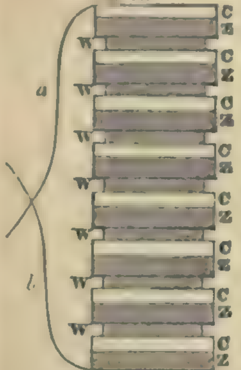
HAVING explained the construction and principles of an elementary battery, we now proceed to notice the various forms which have been suggested as convenient modes of obtaining voltaic electricity for experimental purposes. In so doing, we shall be very brief with those which are rarely used, and shall omit many, the only claim of which to notice would be their novelty, or the ignorance of their inventors.

---

* See *ante*, p. 186.

The first we shall examine is the pile, which was the invention of the celebrated Volta. It is easily constructed by means of zinc and copper plates, of each of which there should be about forty, of a size of two or four inches square. Forty pieces of woollen cloth or brown paper are required, which are to be soaked in strong salt and water, and left to drain. The pile is made by building up the series in the order of zinc, copper, cloth, and so on; a wire is attached to the last plate at each end; and so the pile is completed. One of these is represented in the annexed engraving; in which the letters or initials indicate the position of the metals and the cloth. (See Fig. 38).

Fig. 38.

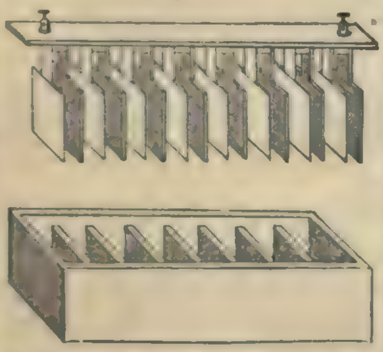


If the two wires, *a b*, be crossed, then a current of electricity is at once produced; and if one of these points be scratched over a file, the other being in contact with it, bright little sparks are afforded. A shock will be felt if the hands are moistened, and grasp the terminal wires.

We need not say that such an arrangement is extremely inconvenient; for it almost surely happens, that the first experiment determines the existence of the pile, by upsetting it altogether: if not, the salt drips from each cloth, and so makes a continuous conductor—destroying the power of the battery. Mr. Cruikshank improved on it by placing the plates, soldered together, in a water-tight box, which was charged with acid and water; and a modification of this form of battery—the cells being filled with wet sand, to prevent spilling the liquid—is still employed by the telegraph companies at the present day.

The next form of battery which came into favour was that of Wollaston's; in which a porcelain trough, to hold the acid water, was employed; and the plates were screwed into a frame. The zinc of one cell was connected with the copper of the next, by means of a copper band, and nuts and screws; and at each end of the frame a binding-screw was placed, which served to hold the conducting wires. One of these batteries is represented in Fig. 39.

Fig. 39.



We have constructed an arrangement of a similar kind; in which each plate was less than the twelfth of an inch from each other; and forty of these will enable the student to try numerous experiments at little cost. A wooden trough, pitched inside, and without divisions, will do to hold the acid.

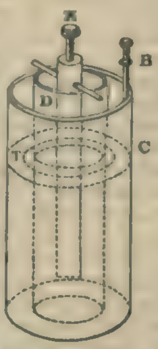
But to all these forms of batteries there is the fatal objection, that the power diminishes from the moment the arrangement is put into action. This arises from a variety of causes, but chiefly from the adhesion of the hydrogen to the surface of the copper plate, which as effectually injures the conducting power as if it were varnished over. For many years electricians combated with the difficulty. Sir Humphry Davy's brilliant discoveries were all made with the instrument we last described. Batteries of immense extent were constructed, which, by their number of cells or the size of the plate, were intended to compensate for these deficiencies. Eventually, Dr. Daniell, of King's College, London, discovered that the adhering hydrogen may be readily removed by presenting the oxide of a metal, in a state of solution, to it; and by the extension of this principle, we can now repeat all the usual class experiments by a battery a few inches long and broad, instead of the expensive and cumbersome arrangements previously in use.

If a piece of common zinc or iron be dipped in sulphuric acid and water, abundance of hydrogen is given off from their surface. But on dissolving a quantity of sulphate of copper (blue vitriol) in the liquid, it will be found that the gas will cease to rise, and a coating of pure copper will be deposited on the metal plate. Now this is an instance of what is called *secondary* action, and may be thus explained. The sulphate of copper contains that metal in combination with oxygen; the hydrogen, rising from the zinc, seizes the oxygen, and forms water, and the metal being set free, falls down as a powder, or is deposited on the iron plate. Omitting, for the present, the action which takes place on the iron or zinc, the following diagram illustrates the changes which occur.

Materials.		Products.
Hydrogen rising from the zinc plate		Water.
Sulphate of copper, composed of	Oxygen	
	Copper	Copper.
	Acid	Acid.

A Daniell's battery is constructed on the above principles. It consists of an outer case of copper, a porous earthenware pot, and a rod of zinc; and one of them is represented in Fig. 40: in which C is the outer copper vessel; D the porous pot; Z the zinc rod, on which is a binding-screw—one also, B, being fitted to the copper cylinder. The zinc being amalgamated, is placed in the porous pot, which is filled with a mixture of one part of sulphuric acid to eight parts of water. The copper vessel is filled with the same acid mixture, which, however, has been first saturated with sulphate of copper; crystals of which are hung on a kind of tray, T, to replenish the solution with copper. If the binding-screws, Z and B, are connected together, a current of electricity is generated; and, after a short time, the inside of the copper vessel is coated with a pink metallic deposit, which is pure copper. This continues as long as the battery is in action, and the strength of the copper solution is kept up. Any number of these cells may be joined together by means of wires inserted in the binding-screws, the copper of one being connected to the zinc of the next, in the usual manner, throughout the series.

Fig. 40.



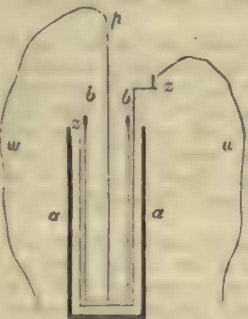
We have tried many modifications of this form of battery; and, for constancy of action, have found it to exceed any other. A common gallipot, a sheet of copper with a wire soldered to it, and a porous pot made of brown paper, with a slip of zinc in the centre, will answer very well for many experiments. In fact, twenty such cells will enable the student to perform many experiments on the small scale, and forms a cheap and effective little battery. Dr. Daniell produced some most brilliant effects with seventy cells, each twenty-one inches high. Some years ago, we fitted up eighty flat cells, each exposing a copper surface of two square feet; which, of course, was a much larger arrangement than that we have just named. The light between charcoal points, and other effects, were of the most astonishing kind.

In using Daniell's battery, it is essential that none of the copper solution should get into the pot holding the zinc; for it would immediately attack the metal, destroy its amalgamation, and lower the power of the battery.

The accidental occurrence of this is common, and is the chief objection to the use of the arrangement.

Grove's Battery.—The next arrangement to which we have to direct attention, is that invented by Professor Grove; which is always employed at the present time for lecture-table purposes, because it is the most powerful of all arrangements yet discovered. The same principles are involved in its construction as in that of Daniell's; but the hydrogen is removed by means of strong nitric acid; and platina, instead of copper, is employed. There is a great advantage in the use of platina, because it is quite unacted on; and the further the affinity of the two metals forming a battery, are apart, the greater is the power of the combination.

Fig. 41.



The annexed engraving illustrates a flat cell of a Grove's battery; in which *a* represents the outer porcelain pot; *z z* a plate of zinc, bent so as to fit into the pot, and rise up on each side; *b b* is a porous pot; and *p* a platina plate; *w w* are wires from each plate. The outer pot next the zinc is charged with sulphuric acid and water; and the porous pot with strong nitric acid. A powerful current of electricity is thus generated, which lasts so long as any nitric acid remains. Fumes of nitrous acid are given off; and this is a serious objection to the battery; for they destroy everything they come in contact with, making it necessary to place the instrument in some position where a strong draught can be obtained.

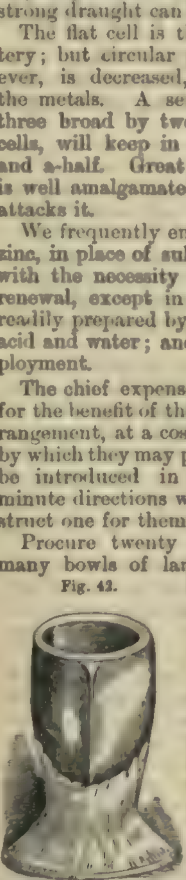
The flat cell is the usual form of arranging the battery; but circular pots may be used: the power, however, is decreased, owing to the increased distance of the metals. A series of flat cells four inches deep, three broad by two wide, with the usual-sized porous cells, will keep in action for about an hour to an hour and a-half. Great care must be taken that the zinc is well amalgamated before use, as the nitric acid soon attacks it.

We frequently employ a strong solution of chloride of zinc, in place of sulphuric acid and water. It dispenses with the necessity of amalgamation, and never requires renewal, except in the addition of more water. It is readily prepared by adding common zinc to hydrochloric acid and water; and many conveniences attend its employment.

The chief expense of this battery is the platina; but for the benefit of those who are desirous of a powerful arrangement, at a cost of not more than twenty shillings—by which they may perform all the experiments which will be introduced in our future pages—we shall give minute directions which will enable our readers to construct one for themselves.

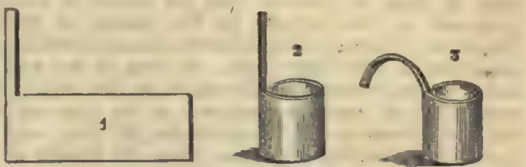
Procure twenty gallipots, two inches high, and as many bowls of large tobacco-pipes. The latter must have the small hole at the lower end stopped up by means of plaster of Paris, and a kind of stand made of the same material, to support the bowls upright, as seen in Fig. 42. It is as well to keep a few of these simple porous pots ready, in case of accident to those in use in the battery. Have cut, by a tin-smith, twenty pieces of zinc, six inches long and two inches deep. (See Fig. 43). The long thin strip may either be cut from the sheet, or be a piece of copper soldered on the zinc; it should be four inches long and half an inch wide. (1.) The sheet must be then bent into the form of a cylinder (2), and the copper or zinc strip is so bent as to form a curve (3).

Fig. 42.



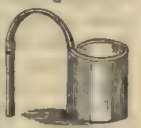
The zinc, when bent into form No. 3, must be amalgamated.

Fig. 43.



There must be soldered on to each of nineteen of the zincs, a piece of platina, a quarter of an inch wide and two inches long. This is easily done by wetting the end of the copper strip with a little muriatic acid, and then dipping it into a little soft solder melted in a ladle. Some of the solder will adhere to the copper; and by now holding it in the flame of the spirit-lamp, and placing the edge of the platina with it in the flame, the tin will melt and the platina will adhere, and must be allowed to cool. The whole, when finished, will appear as in Fig. 44.

Fig. 44.



By this easy plan, all the connections are complete without binding-screws. To one zinc, and to one platina (the first and twentieth of the series), a copper wire of No. 16 gauge, and thirty inches long, must be soldered. These will form the last plates of the series, from each of which the wires will serve to conduct the electricity.

The next step is to put the battery together. First, fill each of the tobacco-bowls with strong nitric acid, and place them in the centre of each gallipot. Take care not to spill the acid over into the outer pot, as that would speedily destroy the zincs. Then place the zinc cylinder, to which the wire is attached, in the first pot; and, in the second, put another cylinder of zinc, with its platina immersed in the tobacco-pipe bowl of the first one, the platina of the third zinc in the bowl of the second pot, and so on throughout the series.

Having thus arranged that the platina of each zinc shall dip into the bowl of the pot immediately preceding it, on arriving at the last pot, the platina, with the wire attached, must be placed in its bowl, and the wires kept steady by driving into a board two nails, round which each of them should be twisted, but kept separate.

The outside pots, containing the zincs, should each now be filled with sulphuric acid and water, in the proportion of one of the former to eight of the latter by measure. The mixture should be cooled before being poured into the cells.

A battery of this description will melt ten inches of thin iron wire; will give a spark of an eighth of an inch long between charcoal points; decompose water rapidly, potass, soda, &c.; and, in short, will answer every purpose which the student can require it for. We have frequently used such an arrangement for purposes of research, extending the number of cells to one hundred, from which some interesting results may be obtained.

Several modifications of Mr. Grove's battery have been proposed, the object having been to do away with the platina. Considerable misunderstanding seems to rest on this point. The first cost of platina is its only cost; and if it be carefully dealt with, and frequently heated red-hot, it will last almost any length of time. We may here observe, that we invariably heat the platina to a red heat before using it, so as to drive away a film of air which always rests on polished surfaces, and which wonderfully lessens the power of the battery by preventing the direct access of the acid to the platina surface.

Bunsen's carbon battery is exactly the same as Grove's, with the exception that some form of charcoal is employed in place of platina. The plate may be cut out of the carbon which forms the inside lining of gas-retorts, or may be made by pounding coke and making it into a paste, with sugar, &c., and pressing it into a mould to obtain the proper shape. The mass is afterwards heated to a red heat, and allowed to cool gradually.

Iron, especially in the cast state, has the singular power of becoming passive—that is, of resisting the action of nitric acid. It may, therefore, sometimes be used in place of platina; and we believe it was first proposed for this purpose by Dr. Callan, of Dublin. There are, however, several inconveniences attending its employment with nitric acid. So long as the acid remains strong, no action takes place on the metal; but, eventually, as water is produced in the iron cell, and the acid is weakened, it often attacks the iron, and the prodigious quantity of fumes given off render it impossible to come near the battery.

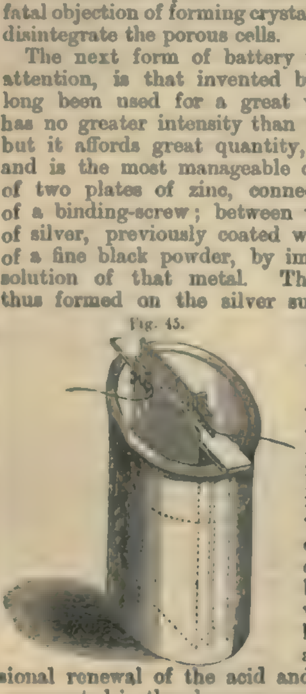
After all the modifications proposed, no arrangement equals Grove's platina battery, in any respect, where great power is required in a small space.

We noticed some very singular results, on employing a plate of copper instead of platina, in the nitric acid cell of a Grove's battery. The heating effects were quite equal to those of the platina arrangement; but, as might have been expected, a most violent action took place on the copper surface; still it maintained a negative state, in respect to the zinc, when tested with a galvanometer, and afforded a strong current for a considerable period. When the nitric acid was saturated with the metal, of course a kind of Daniell's battery was produced. The point which we chiefly noticed, was the fact, that the metal most powerfully acted on still retained its negative character, and the action was neither modified or suspended when the zinc and copper were joined by means of a wire.

In using a Grove's battery, it is of great importance that the platina surface should be perfectly clean. We have already noticed, that the film of air which always coats polished surfaces, frequently prevents the contact between the acid and the metal. Many persons use a charge in the porous parts of equal measures of sulphuric and nitric acid. This, although increasing the power temporarily, does not permit of so great constancy in the action of the battery, owing to the diminished quality of nitric acid.—The mixture must be cooled before charging the cells. Mixtures of nitrate of soda and common nitre (nitrate of potash), with sulphuric acid, have been recommended in place of nitric acid; but they have the fatal objection of forming crystallised salts, which speedily disintegrate the porous cells.

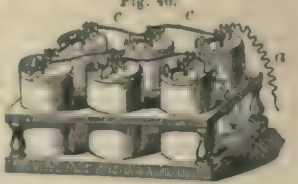
The next form of battery to which we shall direct attention, is that invented by Mr. Smee; which has long been used for a great variety of purposes. It has no greater intensity than the old form of battery; but it affords great quantity, requires but one fluid, and is the most manageable of any kind. It consists of two plates of zinc, connected together by means of a binding-screw; between which is placed a plate of silver, previously coated with platina in the form of a fine black powder, by immersing it in a chloride solution of that metal. The extremely fine points thus formed on the silver surface, throw off rapidly the hydrogen, which otherwise would adhere to the negative metal. The battery is charged with sulphuric acid and water, in variable proportions, according to the power required. This form of battery is perhaps the most suitable for electrotype experiments, especially for beginners; because, if the zincs are well amalgamated, the battery requires no further attention beyond an occasional renewal of the acid and water. A single cell is represented in the above engraving.

Fig. 45.



A number of Smee's batteries may be connected together, and they so form an efficient arrangement for various experiments. The mode of doing this is illustrated in the following cut; in which *a b* represent the end-wires of the battery; and *c c* copper bands, connecting the zinc of one cell with the silver plate of the succeeding one. As a guide to any of our readers who may desire to know the relative power of this and other arrangements, we may observe, that twenty cells of Smee's battery, each plate being four inches square, give the same heating, chemical, and luminous effects as a Grove's battery of four cells, with each platina four inches long and two inches wide. In each instance our measurement refers to the actually immersed surfaces in the exciting fluid.

Fig. 46.



The following results of experiments we have made with various batteries, may prove generally interesting.

1st. Discarding all the old forms of battery, we fitted up, amongst many other arrangements, forty-eight cells of Grove's flat-cell battery, each cell containing sixteen square inches of active platina surface. This battery gave an arch of light between charcoal points of the length of nearly two inches, and nearly three-eighths of an inch thick.

2nd. Seventy-two cells of Daniell's battery in *flat* cells. Each copper exposed a surface of two square feet, and was distant from the zinc about an inch on each side From this we obtained a splendid light of about an inch and a quarter long, and three-quarters of an inch thick.

3rd. Twenty cells of Grove's battery, with platinas in a central porous pot, surrounded by zinc. The platinas were fourteen inches long, and two inches wide. This battery gave a light of about three-eighths of an inch wide, and half an inch long; and made a piece of platina foil, of the same thickness as that used in the cells—one inch wide, and sixteen inches long—red-hot through its entire extent.

4th. Fifty cells of Bunsen's carbon battery. The carbons were one inch and a-half wide, and six inches long. This gave a flame half an inch long, and an eighth of an inch wide.

5th. Fifty cells of Grove's round pots, of the same size as the last, and arranged in a similar manner, but with platina instead of carbon, afforded, for nearly six hours, a light of one inch in length, and rather thicker than the last.

6th. One hundred cells of Grove's battery, of the same as that we have recommended[*] as to size, with tobacco-pipe bowls, &c., gave a light an inch and a-half long, and about as thick as an ordinary bell-wire. The shock from the battery was very severe.

Mr. Gassiot, of Clapham, obtained an arch of light three inches long, by using a battery of 100 cells, of the same size as those mentioned in No. 1, above.

In all these experiments, the effect on the eyes and face was very severe. The battery No. 2 produced a shadow at nine o'clock in the morning, when a piece of stick was held in the direct rays of the sun, shining clearly; and the experiment was tried about the early part of May, 1849.

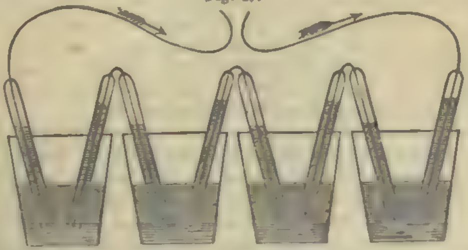
There have been a vast variety of modifications proposed of the different forms of battery we have described; one of the latest being the use of cast-iron, in place of the copper of the old form of battery. We had twenty of these fitted up; the cast-iron being in the form of a flat cell, six inches high, four inches broad, and half an inch wide. Into each, a slip of amalgamated zinc was placed, which was covered with brown paper to prevent contact with the iron; and the iron of one cell was connected, by copper strips, with the zinc of the next in the usual manner. The charge we used was very strong; namely, one part of sulphuric acid to two of water. The quantity of electricity produced was sufficient to render a piece of No. 16 gauge copper wire, six inches long, quite red-hot; but the intolerable stench of sulphuretted hydrogen given off from the battery, compelled each present at the experiment to beat a hasty retreat. The intensity, or chemical effects, were exceedingly feeble.

---

[*] See *ante*, p. 189.

In all the batteries we have described, the effects produced have resulted from the *decomposition* of water. Professor Grove, however, has constructed a gas battery, in which the combination of oxygen with hydrogen, and the consequent production of water, is sufficient to afford a current of electricity. One of these arrangements is represented in the following engraving (Fig. 47); in which each glass contains two tubes, one filled with hydrogen, and one with oxygen. A platina plate is soldered so as to expose its surface to the gas inside the glass. A wire passes from each tube; and the oxygen of one glass tube is thereby connected to the hydrogen of the next, and so on. A wire is brought from the two end-tubes of the series, by means of which the current of electricity is guided to any desired place. The tubes are filled with the gases, in the same proportions, by bulk, as are required to form water; and during the action of the battery, they diminish through their conversion into water. The liquid, which should be dilute sulphuric acid, in each glass vessel, rises, for the same reason, in the tubes. By means of this arrangement, all the ordinary effects of the voltaic battery are readily obtained. Fig. 47 represents one of these singular arrangements.

Fig. 47.

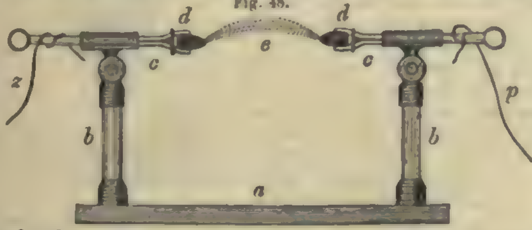


Having thus described the leading forms of voltaic batteries, we shall pass on to examine the various effects which may be produced by them.

THE LUMINOUS EFFECTS OF VOLTAIC BATTERIES.

In the whole range of experimental science, we can find no results of so brilliant a kind as those produced by a powerful voltaic battery. It will be necessary to have at least twenty of either Daniell's, or forty of Smee's arrangements, to repeat the experiments we shall name. To those who can afford larger apparatus, we may mention, that forty cells of Grove's battery, having platinas six inches long and two inches wide, afford some splendid effects; but, for general use, we recommend the simple modification of Grove's, which we fully described in a previous page,* and which will answer every purpose. In all the following experiments, each part of the apparatus and wires, and all the connections, should be kept perfectly clean and polished by a constant and liberal use of sand-paper; and some fine copper wire is useful to tie and connect metallic points, &c. The student should provide himself with such a stand as we described in our remarks on frictional electricity,† or he may easily construct one out of a piece of mahogany; and on this, two uprights should be placed, so as to support two crayon-holders, in which charcoal and other points can be held. One of these arrangements is represented in the above engraving.

Fig. 48.



In Fig. 48, *a* is the table of the apparatus; *b b*, the two uprights; *c c* the crayon-holders; *d d* the charcoal, or other points; *e* the arc of light; *z* the wire from the zinc; and *p*, the wire from the platina of the battery. With such an instrument, the following experiments may be tried.

Experiment 34.—Insert in each crayon-holder a piece of pointed boxwood charcoal, or of the hard carbon formed inside gas-retorts; and having attached the wires of the battery to the crayon-holders, bring the two charcoal points into contact. They will immediately become red-hot; and if they be separated for a short distance, a brilliant arc of flame will extend between the points. This light, which, *par excellence*, is called the Electric Light, far exceeds, in intensity, any other kind of artificial light we can obtain. It is not due to combustion, for it will take place equally well beneath the surface of water, or even in the vacuum of an air-pump. It is due to the fact that fine particles of carbon are transferred rapidly from one pole to the other. This is easily noticed when a powerful battery is employed; for one point gradually increases in size, whilst the other becomes perforated with holes.

We have already given some account of the effects to be obtained by using powerful batteries, at a previous page:‡ but we may remark, that a light produced by fifty cells of a Grove's battery, with platinas four inches long and two wide, is equal to about 1,000 wax candles, of six to the pound, all burning at the same time.

The objections to the use of this light, are its great unsteadiness, and the intensely black shadow which it casts. The latter difficulty cannot be overcome; and every attempt has been made to compensate for the irregularity and intermittence which occurs, by the construction of electric lamps, some of which have already been illustrated in our chapter on artificial illumination.§ We have tried some of the best lamps yet constructed by the most celebrated makers, and others which we have had made ourselves; and we cannot but unhesitatingly observe, that they are all failures in every respect. The objection of expense is of no great force, because the intensity of the light is so great.

The application of the electric light to lighthouse purposes, has, however, been highly successful; and for many months, the South Foreland shone brilliantly with the light produced by the magneto-electric machine, which we shall describe under the head of Electro-Magnetism. At the present time, some parts of Paris are thus lit, and the effect is stated to be very fine. The electric light seems to have what we may call a space-penetrating power, and it can accordingly be seen further in a fog than any other kind of artificial light; its value for lighthouses, on this ground alone, is therefore very great. The colour of the electric light varies according to the materials used as points, between which the arc of flame is produced, as the following experiments will illustrate.

Experiment 35.—Remove the charcoal points, and in their place insert two of zinc. On bringing these into contact, and again separating them, a most beautiful effect is produced. A vivid blue flame, tinged with ruby red, is afforded, and the zinc becomes oxidised, producing, in abundance, a flocky-white powder, which has been called "philosophers' wool."

Experiment 36.—Use two points of thick copper wire: a rich green-coloured light is produced, which has a singular optical effect on all surrounding objects, giving them a deep-green tint. The face of the experimenter presents a most peculiar appearance, which has often a most ludicrous effect on an audience, at the lecture-table. Silver affords a rich green colour, of a darker hue than that of copper.

Experiment 37.—Fix two pieces of stout iron wire in the crayon-holders, and bring their points together, taking care that they do not fuse, and so become solidly united. On separating them, a splendid arc of flame will be produced, and the iron will burn with the most brilliant coruscations. Steel affords a still finer appearance; and if a powerful battery be employed, showers of sparks will sometimes rise from the metal to a height of several feet.

---

* See *ante*, p. 189.

† See *ante*, p. 182; Fig. 30.

‡ See *ante*, p. 190.

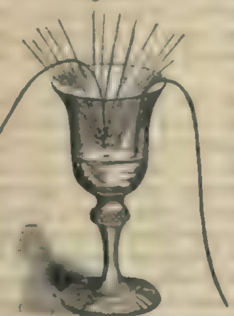
§ See *ante*, p. 136.

Experiment 38.—Pour some mercury into a wine or other glass, and insert one of the wires of the battery. Introduce the other wire of the battery, and then withdraw it to a distance of a quarter of an inch from the mercury surface. A very brilliant flame will be produced, of a bluish-green colour; and the mercury will burn rapidly away, affording dense fumes, which should be carefully avoided.

A modification of this experiment has been applied by Mr. Way in constructing an apparatus, by means of which he obtains a tolerably continuous electric light. Two surfaces of mercury, or one of platina and mercury, are used; and the fluid nature of the latter metal permits of an almost constant distance being kept up between the two terminals of the battery. By this means, one of the great objections to the electric light—its want of constancy—is overcome.

Experiment 39.—Proceed as in the last experiment; but introduce a steel wire, or watch-spring, in place of the copper wire of the battery, and withdraw it a short distance from the mercury. A splendid combustion will ensue, and the sparks of melted steel will be driven about in all directions, affording one of the most beautiful experiments with which we are acquainted. Great care should be taken in the experiment, lest particles of the melted metal enter the eyes—an occurrence which may take place, and which might be a source of injury. The annexed engraving illustrates the mode of carrying out this beautiful experiment.

Fig. 49.



Experiment 40.—Another plan of burning steel, is that of holding one of the wires of the battery in contact with a piece of coke, whilst a file or knife, to which is attached the other wire of the battery, is brought into contact with it, and then separated from it. The combustion is often so powerful as speedily to destroy a good-sized file; and the effect, with a large battery, is frequently of the most brilliant description. The preceding experiments illustrate what is called the *disruptive discharge* of the voltaic battery; and whilst we have selected a few only of the metals, the rest afford very beautiful results.

Some of the experiments we have named may be easily tried under water, by introducing one of the wires into a vessel full of that liquid, and containing some mercury at the lower part, in which one wire should rest. The other wire is to be dipped into the water, and then into the mercury, and to be withdrawn, as in the previous experiments. The discharge will thus take place beneath the liquid, and the singular appearance of flame under water will be presented.

Experiment 41.—Fill a basin with iron or steel filings, and dip one of the wires of the battery into them. Then introduce the other wire, and stir it about roughly for some time. The filings will gradually become heated, and at last red-hot. It is advisable to try this experiment on an iron tray, to prevent any risk of accident, in case the basin may break. Occasionally the filings will become almost fused into a solid mass, owing to the intense heat which is produced.

Experiment 42.—The heat afforded by the disruptive discharge is very great, as may be shown by introducing a piece of platina between the charcoal points of a battery in powerful action, when it will be speedily melted. The diamond may thus be easily burned, or even evaporated away in this manner.

The foregoing experiments will illustrate some of the most interesting of the luminous effects of voltaic electricity. If conducted with a battery of great power, we should warn the reader that the intense light produced is very injurious to the eyes. Indeed, the pain sometimes is intolerable when severe inflammation ensues. Green shades, or spectacles, should always be employed whilst conducting these experiments.

THE CALORIFIC EFFECTS OF VOLTAIC ELECTRICITY.

Having investigated the luminous effects which may be obtained from the voltaic battery, we shall now proceed to describe the heating effects which may be produced from the same source; and shall presume that a battery, similar to that we have already described,* or one of larger size, will be employed.

It will be observed, that the thick wires which convey the electricity from the battery, are not easily heated, except at the points, after they have been in contact. This is because they are sufficiently large to carry the current without affording any considerable resistance to its passage. If, however, these wires are joined together by means of a thin iron wire which is too small to carry the current, and which accordingly affords great resistance to its passage, then a large amount of heat will be set free, and the wire will either be greatly heated, or if the battery be very powerful, the heat will be sufficient to melt even a platina wire. The length of wire heated by any battery depends on the number of cells; whilst the thickness of the wire which may be melted, depends on the size of the plates.

Different metallic wires, of the same thickness, vary in their power of carrying a voltaic current. Copper, as the best conductor, is the most difficult to melt; and iron or platina, which are much inferior in their conducting power, are very readily heated by the voltaic current, and hence are most suitable for illustrating these effects.

The relative conducting power of wires of different metals, or of different thicknesses, may be conveniently illustrated by making a chain of them. Thus, a chain of silver or copper wire, with links of iron wire, will, when made to form part of the conducting course of a powerful battery, present the appearance of an alternation of cold and red-hot wires. Or the thick wires may be nailed to the edge of a table, and each joined by means of finer wire, when the latter, on conveying the current, will be instantly melted. A plan of arranging this is illustrated in the annexed engraving; and the effect, if properly managed, is both instructive and pleasing. The heat thus generated may be made to boil water. The fine wire should be coiled into a screw-like form; and after being attached to the large conducting wires of the battery, it may be introduced into a glassful of water. After a short time, the liquid will commence to boil, and will soon be evaporated off. The best mode of carrying out the experiment is illustrated in the annexed engraving.

Fig. 50.

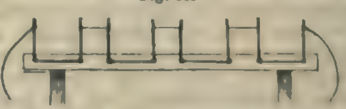


Fig. 51.

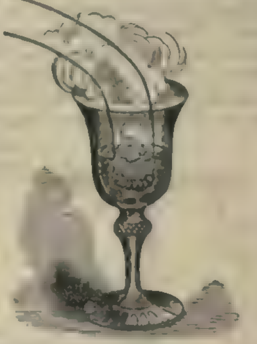
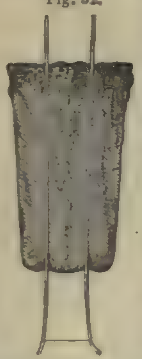


Experiment 43.—The electricity of a powerful battery may be conveyed to any distance by means of properly insulated wires; and for this purpose, gutta-percha answers admirably. The heating powers of the voltaic battery have thus been applied for blasting, military, engineering, and numerous other purposes; and we shall suggest an experiment which will illustrate the plans usually adopted in applying electricity in this manner.

---

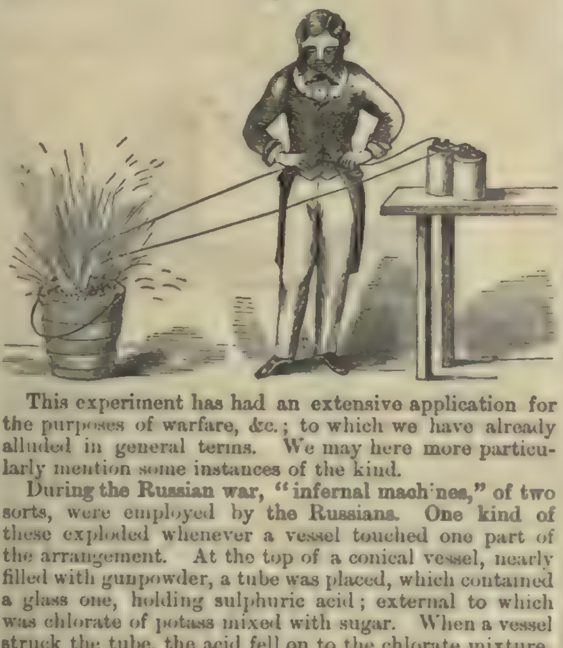
* See *ante*, p. 189.

Fig. 52.



Experiment 44.—A cartridge, closed at one end, and well pitched over, to render it water-tight, is to be filled with gunpowder, and into it may be fitted a cork, through which two thick copper wires have been passed, their inner ends being joined together by a fine iron or platina wire, as represented in Fig. 52. The iron wire thus rests in contact with the powder. The conducting wires are attached to the coarse wires of the cork, and their other ends are laid near the battery. The cartridge is then to be sunk into a pail of water, or a pond, and one of the wires may be connected with one end of the battery. On the other wire being brought into contact with the battery, the current at once passes; the fine wire in the gunpowder becomes ignited, and an explosion at once ensues. The mode of carrying out this experiment is illustrated in the following engraving; in which each part of the arrangement is fully shown.

Fig. 53.



This experiment has had an extensive application for the purposes of warfare, &c.; to which we have already alluded in general terms. We may here more particularly mention some instances of the kind.

During the Russian war, "infernal machines," of two sorts, were employed by the Russians. One kind of these exploded whenever a vessel touched one part of the arrangement. At the top of a conical vessel, nearly filled with gunpowder, a tube was placed, which contained a glass one, holding sulphuric acid; external to which was chlorate of potass mixed with sugar. When a vessel struck the tube, the acid fell on to the chlorate mixture, and, igniting it, soon exploded the powder. These machines were, however, very uncertain in their action, and were superseded by an arrangement in which voltaic electricity was employed as the igniting agent. The plan adopted was precisely similar to that described in our last experiment. The "infernal machine" was sunk in the course which vessels were expected to take; and inside, next to the gunpowder, were two wires, across which was stretched a finer wire. From the main wires two long conducting wires extended to the shore, the ends being placed in close proximity to a voltaic battery. A person was kept watching the progress of any vessel; and when the latter had arrived over the "infernal machine," contact was made with the battery, and an explosion either actually took place or ought to have done so. There is, however, a wonderful difference between trying experiments at the lecture-table, and carrying them out on a large scale. This fact the Russians found out to their cost; and, practically speaking, these voltaic "infernal machines" were utterly worthless.

For engineering and mining purposes, in which every arrangement can be made as complete as possible beforehand, and not necessarily exposed to any chance of disarrangement, this plan of igniting gunpowder for blasting, &c., is of the utmost value. Any amount of powder may be discharged simultaneously. There is no risk of the explosion occurring before proper precautions have been taken, because the whole arrangement is subject to the will of the superintendent. The instant the command to "fire" has been given, the effect takes place; and hence no accident need occur.

As an instance of such an application of voltaic electricity, we may mention the removal of many thousands of tons of chalk from the cliffs of Dover, during the formation of the South-Coast line of railway. Chambers were made in various parts of the rock, and these were filled with gunpowder. Each was connected, by means of wires, with the large battery placed at a considerable distance from the charge: when connexion was made with the battery, the explosion instantly took place.

Colonel Pasley first proposed to apply voltaic electricity for the purpose of blowing up sunken vessels; and this plan has been most successfully adopted in many cases. It is much to be regretted that our miners adopt the old and uncertain plan of the common fuse, which is highly dangerous, and is the frequent cause of loss of life. Generally speaking, nothing is more difficult than the introduction of any new invention; and just in proportion to its value, so the prejudice against it increases. We once met with an old miner, whose chief objection to the use of voltaic electricity, for blasting purposes, was its *great safety;* for he argued, that a diminished risk would tend to lower the wages of the men.

A very ingenious application of voltaic electricity has been made by Mr. Hart, an optician, and philosophical instrument-maker, of Edinburgh, for the purpose of lighting chandeliers, and other gas arrangements which are inaccessible by ladders. He arranges over each burner two main conducting wires, connected by means of a fine platina wire. On the ignition of the latter by the voltaic battery, the gas is simultaneously lit in each burner; and by means of an electro-magnet, the platina wire is instantly removed from the flame when the latter is produced. This, of course, prevents the destruction of the platina by the impurities which coal gas always contains. The experiment may be easily repeated by means of a single gas-burner: indeed, a tallow candle may be readily ignited by a wire heated white-hot by means of the voltaic battery

THE CHEMICAL EFFECTS OF VOLTAIC ELECTRICITY.

As this subject will be fully dealt with under the head of Electrotyping, we shall confine our remarks to the pure philosophy of the question; and so prepare our readers to enter into those details which the applications of any branch of science always afford.

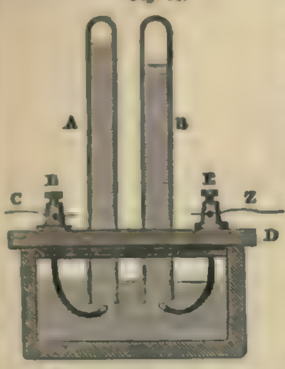
We have already stated, that a voltaic battery, or the single cell, depends for its action on the fact that chemical decomposition takes place in some part of the arrangement; and to this is due the evolution of free electricity. If the terminals of a single pair of plates, or of one cell of any form of the voltaic battery, be immersed in a solution of any salt, the acid always passes to one side, and the base to the other; and this is so universally the case, that definite laws, of what has been termed electro-chemical decomposition, have been discovered, which govern every case in which chemical changes take place in the presence of free electricity.

The simplest instance of the chemical effects of a voltaic battery to which we can refer, is that of the decomposition of water, which is a type of all electro-chemical changes. For the purpose of trying the following experiments, four cells of Grove's battery, or ten of Daniell's or Smee's, will be required; and presuming that the student has supplied himself with any of these arrangements, we shall proceed to investigate some interesting phenomena. The wires proceeding from the battery should be connected with a piece of platina foil; because, as that is unacted on by most of the substances to which we shall refer, no secondary or disturbing cause will interfere with the effects resulting from the action of electricity on the chemical compounds we shall examine.

If the wires proceeding from a battery furnished with platina poles, are dipped into a solution of sulphuric acid in water, the platina surface alone being exposed, abundance of gas will be given off from each plate. If these gases are collected separately, it will be found, that one is pure oxygen, and the other hydrogen gas; and these are given off from the platina terminals in the proportions required in their reunion to form water. A convenient arrangement for collecting the gases separately is represented in the following figure. By such an instrument, the two gases, which when combined produce water, may be collected apart from each other, and their characters may be readily examined. The left-hand tube, in Fig. 54, is supposed to be receiving oxygen gas; and that on the right hand is being filled with hydrogen, the other constituent of pure water. By bulk, one of oxygen to two of hydrogen is given off; but, by weight, one pound of hydrogen to eight pounds of oxygen are required to produce nine pounds of water.

If the gas (oxygen) received in the left-hand tube be tested, it will be seen that the combustion of a taper or match is rapidly increased by it. On the contrary, the gas (hydrogen) received in the right-hand tube, will not support combustion; and, indeed, it will at once catch fire if a light be presented to it.

Fig. 54.



A and B represent the two tubes intended to receive the gases; C and Z the wires coming from the copper or platina, and zinc ends of the battery, and tipped with platina; D, a cover in which the tubes rest; E E two binding-screws, through which the battery wires are passed.

It is found, that these gases, evolved during the decomposition of water by electricity, always present themselves in the same part of the instrument. For instance, hydrogen is invariably found at that terminal or pole (as it is frequently called) which ends the wire proceeding from the *zinc* end of the battery; whilst oxygen is always noticed as proceeding from that terminal, or pole, which is connected with the *platina*, or *copper* plate of the battery. It hence follows, that that pole which proceeds from, or ends the positive plate of a battery, is negative to that which terminates or proceeds from the negative plate of the battery itself. The wire or plate connected with the negative plate of a battery, is positive in any solution undergoing decomposition. We may simply state, that the poles or terminals of a battery, when immersed in any solution undergoing decomposition, have opposite electrical states to the plate of the battery from which they proceed; and this results from the laws of induction, already explained in a previous page.*

These poles, or terminals, have had other names applied to them. Dr. Faraday has suggested the term "electrodes," from the Greek "odos," a way; and the negative pole, or that terminating the wire from the zinc end of the battery, has been called the "zincode," or "cathode;" while that proceeding from, and ending the wire of the copper or platina plate of a battery, has been termed the "platinode," or "anode." These terms include the idea of the "passage" of a "current" from the copper pole to that of the zinc—a question on which we have already made some remarks in our earlier pages.†

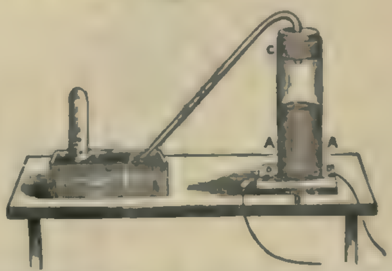
The changes which occur, both electrically and chemically, may be represented as in the following diagram:—

No. 1	OH	OH	OH	
No. 2	O	HO	HO	H

In No. 1, we observe the constitution of pure water represented as a combination of oxygen (O) with hydrogen (H); but when the poles of a voltaic battery are placed in the liquid, then the oxygen of one atom is set free, and its hydrogen combines with the oxygen of that next to it; and so on, until hydrogen is given off from the last atom in the series. The two gases obtained from water may be collected together by a very simple piece of apparatus. Into a glass tube or a gas chimney, fit two corks, so that when finally fixed they shall be water-tight. On each side of the inside of the glass put a small piece of platina foil facing each other, and extending half an inch outside of the glass. These pieces will serve the double purpose of conductors both inside and outside. Now press one of the corks into the glass, and so keep the foil in its place. The small pieces of platina on the outside may be bent outwards, and are intended to receive the conducting wires of the battery. This will complete the bottom part of the arrangement. Into the top of the glass fit the other cork, in which has been fixed a bent pewter or glass tube, and through which the gas produced will afterwards be carried away. The glass should previously be half filled with some acid water, and may then be cemented, by means of some sealing-wax, to a piece of wood, which will serve as a stand. Fig. 55 represents the arrangement we have described.

On bringing the wires into contact with D D, the water inside the glass will be decomposed; and if the bent tube be dipped beneath the water in a pneumatic trough, the two gases may be collected in any vessel, after the usual manner. When the tube is filled with gas, apply a light, and an explosion will at once take place, and water will be formed.

Fig. 55.



A A, two pieces of platina foil, part of each extending outside the glass; B, the bottom cork, to keep A A in their place; C, a cork holding a tube through which the gases are to pass; D D, the two outside pieces of platina foil, on which the wires of the battery are to be placed, and by which the electricity enters and leaves the water.

The philosophical instrument-makers sell an arrangement of a similar, but more complete kind: the student, however, who has to consult economy, will find that which we have described to answer every purpose. Some patents have been taken out, the object of which has been to apply the mixed gases thus obtained to illuminating purposes. The mixed gases may be produced at the rate of 200 cubic inches per minute, by means of a Grove's battery of five cells, each platina exposing one hundred square inches of active surface; and if the gases so afforded are passed through a Hemming safety-jet, and their flame be thrown on a cylinder of lime, the ordinary lime or Drummond light will be produced. We have frequently tried an arrangement of this kind; but much prefer the ordinary mode of producing oxygen and hydrogen, and burning them from gasometers or gas-bags. Independent of any other consideration, the expense of the voltaic battery is a serious item, in a commercial point of view, in this application.

If two pieces of platina, attached to each end of the battery, be immersed in a solution of any neutral salt, chemical decomposition at once ensues, and the acid and the base are readily separated from each other. An ordinary tumbler, or any other glass vessel, may be employed. It should be divided by means of a stout card, as shown in Fig. 56; in which the two platina plates, and the wires proceeding from the battery, are also represented.

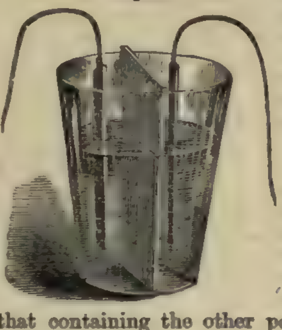
Experiment 45.—A solution of common salt in water, coloured by a little litmus, may be used. The chlorine, set free by the voltaic current, will bleach that side of the liquid in which the wire from the platina of the battery is immersed, whilst the other side will retain its blue appearance.

---

* See *ante*, p. 178, *et seq.*

† See *ante*, p. 160.

Fig. 56.



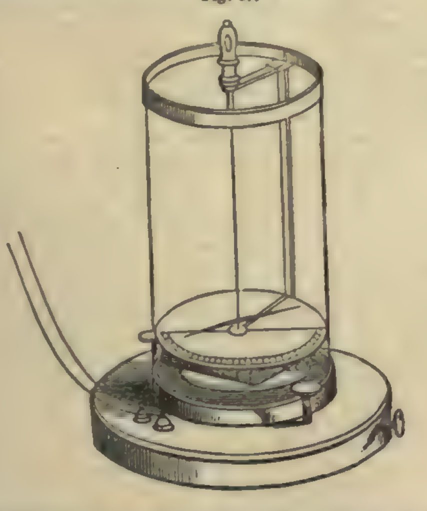
Experiment 46.—Employ a solution of sulphate of soda, also coloured with litmus. The salt will be decomposed; the side in which the wire from the zinc is immersed, will retain a blue colour; whilst that containing the other pole, will present a red appearance, from the liberated sulphuric acid acting on the litmus.

Experiment 47.—Dissolve some iodide of potassium in water, and add a little arrowroot (nearly pure starch). On inserting the two poles of the battery, the iodide will be decomposed, and one side of the liquid will turn to a deep-blue colour, owing to the liberation of free iodine.

The above are instances of chemical decomposition effected by means of the current of electricity passing through the liquid; and we may here remark that liquidity is essential for such changes. We shall, perhaps, draw too largely on the chemical knowledge of some of our readers, if we state, that a direct connection exists between the equivalents of the metal dissolved in the battery, with the amount of the elements set free in the glass decomposing-vessel. What we mean is simply this—for every thirty-two grains of zinc dissolved in *one* cell of a battery arrangement, one grain of hydrogen, and eight grains of oxygen, are set free during the decomposition of water. If five battery cells are used, then five times as much zinc is consumed during the evolution of one grain of hydrogen and eight of oxygen; so that the quantity of gases evolved by the action of a battery in decomposing water, is a measure of the quantity of electricity which is set free.

There are other modes of ascertaining the strength of a voltaic current; and although such would be better described under the head of Electro-Magnetism, we may just state, that the galvanometer, by the deflection of a magnetic needle, when a current of voltaic electricity passes over it, is often employed as a test of the presence, and also as a measure of the amount, of electricity passing over its wires. One of these instruments is represented in the following engraving.

Fig. 57.



Two wires may be observed on the left-hand of the cut: these convey the electricity from the battery. A coil of fine covered wire is wound repeatedly over, but not touching, a magnetic needle; and just in proportion as the quantity of electricity in the current is great, so the needle is deflected from zero, or 0°. This deflection rarely exceeds 70°, even when a powerful battery is employed. But neither this instrument or the decomposing apparatus give any measurement of the intensity of the current. This is best arrived at by interposing a length of some bad conductor, such as pure water, between one of the wires and the galvanometer, or the decomposing apparatus. The latter has been somewhat ambiguously termed, by way of distinction, a voltameter.

The secondary results of voltaic action in the decomposition of metallic solutions, is so elaborately and practically dealt with in the next chapter, by Mr. Gore, of Birmingham, that we shall not enter into any explanation of the subject. Our readers will have the opportunity of studying the theory and practice of electrotyping, plating, and gilding, in all their details. We have been compelled to make some alterations in the original paper, because we have already explained many points in our previous pages. All essential matters, however, have been retained; and we have made several additions on processes which late discoveries and inventions have introduced to public notice.

In the early part of this century, Sir Humphry Davy created a great sensation in scientific circles, by the publication of his researches in electro-chemistry. He found that, on bringing the two poles of a voltaic battery into contact with a piece of potash, that substance was decomposed, and a metal was liberated which he called potassium. He extended his investigations, and eventually obtained sodium, barium, and other metals by a similar process. The student may try the following experiments, which will illustrate this interesting discovery.

Experiment 48.—Place a small piece of fused potass on some platina foil, which must be connected with one pole of the battery; and bring the other pole, which should be a piece of platina wire, into contact with the potass. Chemical decomposition will soon take place; hydrogen will be given off, and potassium will be set free. If a little mercury be used instead of the platina foil, an amalgam of that metal with the potassium will be produced; and a little of this, if placed in cold water, will show the presence of potassium by the production of hydrogen gas, through the metal decomposing the water, and seizing its oxygen to form potass.—A similar experiment may be performed with soda, when the metal sodium will be produced. If the air be very dry, the potass should be breathed on, so as to make it a conductor by the moisture which it absorbs, as, in the dry state, its power of conduction is very slight.

By these experiments, it is shown, that potass, soda, &c., are oxides of metals, similar in constitution to the rust of iron, red lead, &c. At first these results were chiefly of interest to philosophers only; but during the last few years, the cheap production of sodium has led to that of aluminium, a metal obtained from common clay, which has now come into extensive use for a great variety of purposes. Our readers will not fail to observe how valuable are those philosophical researches which at first seem to have no practical result, but which, by patience and skill, may eventually turn out to be of the utmost commercial and social benefit.

Electricity, it is believed, has a great influence in producing many of those valuable gems which adorn jewellery; and many attempts have been made to produce the diamond, &c., by electro-chemical means. It has been ascertained that a current of free electricity always exists in mines from which metals are obtained. This, however, may be caused by the chemical changes which air and moisture always produce on metals and their oxides. Mr. Crosse and others have succeeded in producing minute crystals of some minerals, by long-continued, intense voltaic currents; and for this purpose small quantity is required. Indeed, a battery composed of small plates in large numbers, charged with common water, is as effective as any of the powerful arrangements to which we have already alluded. Such an arrangement is termed a water battery; and, for the purposes we have named, its two poles, which should be platina wires, are to be immersed in a mineral solution. As natural processes are always slow, so the results of the action of the electric current, in these cases, must be greatly prolonged. A microscope is often required to detect the first formation of crystals; and much patience and care are required to obtain a successful result.

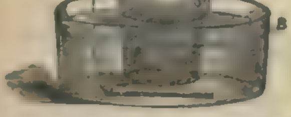
By means of a moderate battery power, some very interesting results may be obtained from various metallic solutions. Amongst them we may mention the production of brilliant metallic rings on a steel plate; and the deposition of metals in veins similar to those we observe in nature. The two following experiments illustrate each process.

Experiment 49.—*Nobili's Rings.*—These are most beautiful rings, formed on a piece of steel by means of a small galvanic battery. To produce them, place a sheet of polished steel in a plate containing a solution of sugar of lead, and attach the steel plate to the wire coming from the *platina* end of three cells of Grove's battery. Hold the wire from the zinc end in the solution, within an eighth of an inch over the centre of the steel plate. Beautiful rings of the oxide of lead will be at once produced; and in a few seconds the steel should be removed, and carefully washed in distilled water. This is one of the prettiest effects produced by a galvanic battery, and the colours obtained are similar to those observed on mother-of-pearl. Care must be taken to make no mistake with reference to the wires in placing them in the solution.

The next experiment, if carefully performed, illustrates the formation of metallic veins, such as are found in copper mines.

Experiment 50.—*To produce Minerals by means of Electricity.*—For this purpose, half-fill a garden-pot, six inches deep, with plaster of Paris, by stirring some of this powder in a basin of water, and pouring the mixture into the porous pot, where it must remain until it becomes solid. Solder a copper wire to a piece of zinc and a piece of copper, so that the two metals may be placed, one in the inside of the pot, and the other so that the pot may rest on it, and cover the intermediate wire with sealing-wax. Fill a basin, say to a depth of four inches, with a strong solution of sulphate of copper, adding to it a little sulphuric acid. In this basin place a piece of copper, and on the metal place the pot. Bend the wire so that the zinc may rest inside the pot, and touching the plaster of Paris; and fill the inside with a solution of common salt. Having done this, throw a cloth over the whole arrangement, and leave it for two or three weeks, replacing the loss of liquid, both in the basin and pot, by occasionally adding some water. At the end of the time named, on breaking the pot and plaster in half, it will be seen that the copper has crept in and assumed various beautiful forms. In some places it will be observed in crystals; in others as a layer of a rich blue or purple colour; and if the lump be dried, it will form a complete counterpart of a natural mineral. We have succeeded with iron and other metals, by using them instead of copper, which, however, we have given as being the easiest to commence with. To assist in constructing one of these interesting arrangements, we annex an engraving, and a description of the various parts to which we have referred.

Fig. 56.



B is the basin holding the copper solution; C, the plate of copper on which G, the garden-pot, rests; P, plaster of Paris in the pot; W, the copper wire covered with sealing-wax; Z, zinc plate inside the pot, hanging in the solution of salt, S.

Considerable sensation was produced, some years ago, by the statement, that insects of the acarus kind had been produced by Mr. Crosse, through long-continued voltaic action. Mineral solutions, after being electrised a few weeks, seemed to produce an abundance of these insects; although great care had been taken to prevent extraneous circumstances from interfering with the experiment. We believe that Mr. Weekes, of Sandwich, repeated these experiments, and obtained partial success. The idea of such a method of producing living creatures was so repugnant to theory and common sense, that it has been supposed some eggs of the insect had been accidentally present, and that time, electricity, and heat had eventually caused them to be hatched. We repeated the experiments exactly as they were described by Mr. Crosse, with the exception that every possible care was taken to prevent the access of fresh atmospheric air, which is always loaded with germs of all kinds; and, like most other experimenters, we met with no success. We can only hint, to say the least, that it was a most strange occurrence that electricity should produce a tolerably perfect organised insect, such as those of the acarus kind. One would naturally suppose, in the absence of all extraneous interfering causes, that nature would have presented us with creatures of a more elementary kind of organisation as the result of electric action. We must, however, dismiss the subject, and leave our readers to draw their own inferences as to the results and the circumstances which were connected with the experiments.

The "results," published by Mr. Crosse, have actually been quoted as instances of spontaneous generation, by some who, however, have been more noted for the boldness than the exactitude of their speculations.

THE PHYSIOLOGICAL EFFECTS OF VOLTAIC ELECTRICITY.

In our remarks on the effects of frictional electricity on animals, or on the human frame, it will be observed that the shock obtained from the Leyden jar is sudden, and only occurs each time the jar is discharged. The shock from the voltaic battery, on the contrary, is continuous as long as the arrangement is kept in action, and its power depends conjointly on the number and size of the plates, together with the amount of chemical action which is going on in each cell. The sensation produced, also materially differs from that of the Leyden jar: an intense cramp of the muscles is felt; and, if a very extensive series be employed, it will be impossible for any one to leave hold of the wires proceeding from the battery, owing to the contraction of the muscles of the arm which ensues.

Forty or fifty pairs of plates in the pile, or the same number of Smee's or Daniell's arrangement, produce considerable effect on the muscular system of one person. But if a number of persons be joined together, the power of the shock will be greatly diminished, unless the hands are well moistened with salt and water. Fifty cells of Grove's battery produce a severe shock; and it is necessary that that portion of the wires which have to be touched during the experiments, should be covered by some non-conducting substance, than which nothing is better than brown paper.

Voltaic electricity has been frequently employed for medical purposes, in cases of drowning, asphyxia, from inhaling carbonic acid gas, paralysis, &c.; and it has the advantage of being easily regulated to any extent desirable, with respect to the power of the shock. The coil machine, which will be described under the head of Electro-Magnetism, is almost invariably employed for this purpose, however, at the present time.

Some remarkable experiments have been tried on the bodies of men and animals immediately after death, by means of powerful voltaic batteries; and the most curious which we have met with, is that related by Dr. Ure, in his *Dictionary of Chemistry*, under the head of Galvanism. The body of a murderer, recently executed, was the subject in this case; and by sending the current through various parts of the body, many of the appearances of life were produced; in fact, had the body not been drained of blood, there is no doubt that life would have been restored. We must refer our readers to the work named, for full particulars; but may remark, that the contortions of the face, and the contractions of various muscles so produced, were of such a horrible character, that most of the spectators had to leave the room from sickness or faintness. Such experiments may easily be repeated on rabbits, cats, and dogs, immediately after death. In one experiment which we tried by a powerful battery, a rabbit leaped several feet from the table on which it was placed, which was caused by the powerful contraction of the muscles of the leg. By a judicious insertion of the poles of the battery in different parts of the body, any set of muscles may be called into play, and the effects almost invariably present the appearance of restored life in the subject.

ANIMAL ELECTRICITY.

In the previous chapter, we confined our remarks on this subject to describing some particulars in reference to electrical fishes. We shall now place before our readers some facts relating to the effects on, and the production in, the bodies of animals, of free electricity.

Electricity and magnetism have always been charged with being the cause of various phenomena observed in animals, to which no other could be assigned : hence, we have had the vagaries and absurdities of "mesmerism" and "animal magnetism" continually thrust on public notice. We can only spare space to remark, that those who have been most prominent in support of such subjects, have generally been equally eminent for their ignorance of true science, and have, according to the old adage, found plenty to admire them. It is a most unfortunate failing of our mental powers, when in an untrained state, that we are always ready to believe that which is hardly credible, in preference to well-substantiated facts and conclusions which may be readily demonstrated—the imagination frequently overruling the power of our reasoning faculties.

It has long been known, that electrical may, in some cases, be substituted for nervous action ; and thus, many years ago, it was shown that a piece of zinc, and one of platina, might be inserted between the previously divided nerves of the stomach of a rabbit, and that digestion, and other vital processes, continued just as if no alteration of the continuity of the nerves had occurred.

Aldini has made numerous researches in this branch of science ; and the fact of free electricity in the current form being always present in the body, and passing between the nerves and muscles, has been satisfactorily proved. Indeed, a voltaic battery may be made, and many experiments can be tried, by means of the nerve and muscle recently obtained from the living animal, if such are arranged in a similar form to that of the voltaic pile.*

Many persons may exhibit a kind of double set of phenomena in reference to electricity. Some, indeed, may have the hair and skin excited by friction, so as to afford sparks in abundance. This, however, is chiefly observed in persons of a phlegmatic temperament, having a harsh skin, and a freedom from excessive perspiration of the body. Others, of a sanguine and nervous temperament, more readily exhibit free electricity in the nervous system, arising, as far as we know, from chemical action. Thus we may rank individuals under the separate classes of those presenting the phenomena of frictional and voltaic electricity respectively.

That electricity has a decided influence on the general health, is admitted on all hands. Every one experiences in foggy weather, or at times when the atmosphere is surcharged with electricity, a peculiar heavy and depressed feeling. The sanitary tables, now so freely published, when taken in connection with simultaneous electrical observations, indicate that electricity has a definite relationship, in some way or another, with the health and diseases of a community.

This fact, however, has been sometimes extended far beyond its legitimate limits ; and there have been those having some claim to a scientific reputation, who have not hesitated to avow their belief that electricity is the vital principle. Had they affirmed the same of caloric, their views would have had a more feasible or plausible appearance ; for it is an admitted fact, that life cannot be maintained unless a certain amount of animal heat is kept up. It is, however, unnecessary for us to discuss this question. The common sense and experience of our daily lives, apart from the more exact teachings of science, are sufficient to show, that however active and necessary certain agents may be for the purpose of producing definite results, it by no means follows that such are primary causes. The celebrated Stephenson once asked a friend what it was that caused the rapid motion of one of his locomotives. The reply was characteristic of an experimentalist—the combustion of the fuel in the furnace was assigned as the reason. Stephenson, however, most expressively corrected this ; and referred to the fact, that all the heat and effect produced, were due to those rays of heat and light which had first been absorbed from the sun, and were given out again with their full force in the furnace ; although, perhaps for thousands of years, they had laid dormant in the bowels of the earth. In the same spirit, the true philosopher, whilst investigating and admiring the chain of second causes, constantly operating in the course of natural phenomena, refers all for their first origin, to that Great First Cause who called them into being. As glimpse after glimpse is obtained of the infinity of creative power, which our limited intelligence can but feebly comprehend—the humble but earnest inquirer is compelled, in reverence, to exclaim—"Oh Lord, how manifold are thy works ; in wisdom hast thou made them all."

---

* See *ante*, p. 188 ; Fig. 38.

CHAPTER III.

ELECTRO-METALLURGY.

The following paper, written by Mr. Gore, of Birmingham, affords full details of the theory and practice of the arts of electrotyping, gilding, plating, &c. As many of the subjects which were discussed in the original, have already been mentioned in the preceding pages, the editor has omitted such portions, and has made various alterations and additions in reference to numerous processes, and their practical details, which he trusts may be of value both to the student and general reader.

THE THEORY OF ELECTRO-DEPOSITION.

Introductory Remarks.—As the ultimate object of this chapter is to enable the reader to work in an electro-plate manufactory in a commercially successful manner, we shall endeavour to include within its pages, as far as the limited space will allow, every portion of the subject calculated to assist him in obtaining that result, excluding from it every other which does not contribute towards that object.

With this view we shall explain the *principles* or *theory* of electro-deposition, because every workman in an electro-plate manufactory is certain to meet with difficulties, which no amount of practical knowledge or experience will enable him to overcome without a perfect knowledge of the theoretical principles. These difficulties may be new ones, such probably as he has never seen before ; and no doubt, in some cases, such as no one else has ever seen : a knowledge of the theory will here enable him to apply principles, and suggest remedies, some of which are almost sure to be successful.

We shall also include the *practice* of the subject ;

because, after all, its success depends on careful manipulation; for with ever so perfect a knowledge of principles, without a perfect knowledge of the application of those principles in the form of practical rules and manipulation, success cannot possibly be attained. With the same end in view, we shall avoid saying anything about the history of the subject, or the claims of rival discoverers or inventors—these being subjects for the historian. Neither shall we say much about the electro-deposition of rare metals, or about any collateral branches of the subject, excepting only so far as they are capable of illustrating the subject in a direct manner, or of otherwise furthering the object in view.

To enable the reader to master the subject as he proceeds, we have so arranged it that every portion shall be, so far as it goes, complete in itself, requiring no anticipatory knowledge of more advanced parts to enable him to understand it.

The only arrangement which admits of this important object being attained, is to explain the theory before treating of the practice, and by arranging the theory in an *inductive* order. In other words, we shall commence with the various classes of facts on which electro-deposition is founded, and ascend from these to the general laws or principles, chemical or electrical, which govern them. Proceeding from the theory to the practice, arranging all in a *deductive* order, and applying theoretical principles in the form of practical rules, the results cannot be other than successful. Beginning with the more general rules which apply to all electro-deposition processes, and to the electro-deposition of all metals, and proceeding, step by step, to those more special rules of manipulation which are required for the working of particular metals and solutions, the necessary requirements for the production of the more difficult substances and more complicated works of art will be attained. Through the whole chapter, the reader will thus be led gradually from the most common and well-known facts, to the most complex and difficult applications of electro-deposition.

In accordance with this plan, the subject will commence with a review of such facts of electro-deposition as every man possessing the few necessary materials, which are easily procurable, may readily verify for himself. On these facts the whole subject throughout will be based. From them we shall proceed to the circumstances or *conditions* under which they occur; namely, the *causes* of electro-deposition. The principles will be inferred from the facts as we proceed, until we arrive at the more abstract laws of the phenomena.

The facts will be based on numerous experiments, in which instances where deposition does occur, as well as experiments in which it does not occur, will be cited. These investigations will satisfy the reader, that in all cases where deposition does occur, certain conditions are invariably present; and where it does not occur, one or more of them is invariably absent; and, therefore, that the conditions observed are essential to the production of the phenomena. Another and more ultimate reason for mentioning negative as well as positive instances is, that, in practical working, it is nearly as important to know what will prevent deposition, as to know what will produce it.

The following table exhibits the phenomena of electro-deposition, arranged in an inductive order, suitable for teaching the subject theoretically, and without immediate reference to its practical applications. The first portion of the table contains the *facts* of electro-deposition, divided into seven classes, under which may be ranged the whole known facts of the art. The second portion contains the *principles* or *conditions* under which those facts are manifested; these are also divided into seven classes, which are capable of including all the known conditions or causes of electro-deposition.

A.—FACTS.

1. Deposition by one metal and one liquid.
2. Deposition by two metals and one liquid.
3. Deposition by one metal and two liquids.
4. Deposition by two metals and two liquids.
5. Deposition by connecting either of the foregoing arrangements (except the first) with a separate depositing liquid.
6. Deposition by connecting other sources of depositing power with a separate depositing liquid.
7. Deposition by combinations of the foregoing.

B.—PRINCIPLES.

1. Chemical conditions of deposition.
2. Electrical conditions of deposition.
3. Thermal conditions of deposition.
4. Mechanical conditions of deposition.
5. Mathematical conditions of deposition.
6. Logical conditions of deposition.
7. Ontological conditions of deposition.

This arrangement has been used with much success in teaching the theoretical part of electro-deposition, as it enabled the pupils to understand each portion clearly as they proceeded. The plan adopted was—

First, to exhibit before the pupils numerous experiments of each class of facts in succession, including positive cases in which deposition did occur, as well as negative ones in which it did not occur.

Second, to place each of the theoretical principles in succession before them in the form of a hypothetical question, referring them to the various facts on which it is founded, and leaving them to observe for themselves whether or not the principle there stated was borne out, allowing them to draw their own conclusions. By this method they were soon led to observe, that, wherever deposition occurred, certain conditions were present, and that where it did not occur those conditions were absent.

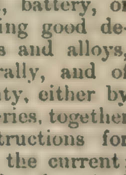
When treating of the laws and principles of deposition, the reader will be referred back to the facts upon which they are based; so, when describing its practical applications, he will in like manner be referred to the laws or principles for his guidance: his knowledge of the practice will thus be based in a great measure upon the principles, as the principles will be deduced from the facts, which, as we have said before, are within the reach of every one to repeat and prove for himself.

The practical part will treat, in succession, of the general rules for working all the different processes of washing or dipping, whether by single cell, battery, or other process. The requisites for preparing good depositing solutions, both for simple metals and alloys, with methods of making solutions generally, and of working them; suitable sources of electricity, either by the magneto-electric machine or other batteries, together with their construction; as well as instructions for regulating the quantity and intensity of the current; regulating the quantity and quality of the deposited metal; cleaning and preparing metallic surfaces for receiving adhesive and non-adhesive deposits; copying works of art in various substances; elastic moulding; preparation of non-conducting surfaces to receive a deposit; multiplication of works of art by deposition; deposition, by the various processes, of such metals and their alloys, as antimony, bismuth, zinc, cadmium, tin, lead, iron, cobalt, nickel, copper, brass, German silver, mercury, silver, gold, platina, and palladium; chemical relations of the cyanides of gold and silver; manufacture of cyanide of potassium; recovery of gold and silver from damaged solutions; and a full list of patents upon electro-deposition will be fully treated on as we proceed.

THEORETICAL DIVISION OF THE SUBJECT.

1. *Facts.—One Metal in One Liquid.*—There are various modes in which deposition of one metal upon another may take place; and they may be classed as follows:—

Fig. 59.



1st. By the simple immersion of *one* metal in *one* liquid (Fig 59); namely, by putting the metal to be coated into a solution of the metal to be deposited, and allowing it to remain a longer or shorter period of time, the liquid being at a suitable temperature; for instance, if we immerse a piece of clean iron in a solution of sulphate of copper, it will become coated with copper; but if we immerse a piece of silver in that liquid, it will not become so coated.

2nd. *Two Metals in One Liquid.*—By the immersion of *two* metals in *one* liquid (Fig. 60), the two metals being in contact with each other: for instance, if we connect a piece of silver A and a piece of iron B together, and immerse them in a solution of sulphate of copper C, the silver will become coated with copper as well as the iron; but if a piece of silver in contact with a piece of gold or platina be immersed in the same liquid, it will not become coated. We have already seen, that silver immersed alone in such a liquid, will not receive a deposit of copper.

Fig. 60.

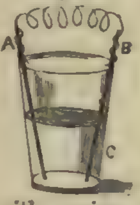


Fig. 61.

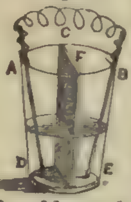
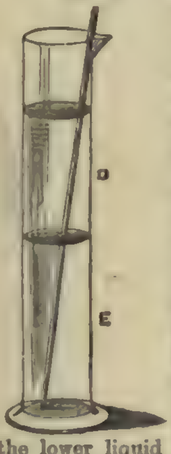


3rd. *One Metal in Two Liquids.*—By the immersion of *one* metal (*i.e.*, one *kind* of metal) in *two* liquids D and E (Figs. 61 and 62), the liquids being prevented from mixing with each other either by a porous partition F (Fig. 61) of bladder, thin wood, unglazed earthenware, or other porous material which will allow the two liquids to touch each other through its pores; the piece of metal being either bent so as to dip into each liquid, or cut into two portions, and its two ends united by a wire C, the end or piece to receive the deposit being immersed in one liquid, and the other piece in the other liquid (Fig. 61); or the two liquids being put in a deep narrow vessel, the heavier one being poured in first, and the lighter one poured carefully above it so as not to mix them together, and the piece of metal being in the form of a rod or wire placed vertically in the two liquids (Fig. 62); for instance, if the lower liquid consist of a solution of sulphate of copper, and the other of dilute sulphuric acid, and a piece of copper be immersed in both liquids, that part of it which is in the sulphate solution will become coated with copper, whilst that in the acid liquid will be partly dissolved; but if, instead of copper, we use a piece of platina, it will neither be dissolved nor receive a metallic deposit.

Fig. 62.



4th. *Two Metals in Two Liquids.*—By the immersion of *two* metals A and B (Fig. 63) in *two* liquids, D and E, the two being, as in the last arrangement, either separated by a porous diaphragm F, or poured one above the other, the two metals being immersed one in each liquid, and connected together by a wire C: for instance, if one liquid be dilute sulphuric acid, and the other a solution of sulphate of copper, and a piece of copper be immersed in the dilute acid, and a piece of silver in the metallic solution, the two metals being thus in mutual contact, the piece of copper will dissolve, and the silver receive a deposit of copper; but if we immerse a piece of platina in the dilute acid with the silver in the sulphate solution, the platina will not dissolve, nor the silver receive a metallic deposit.

Fig. 63.

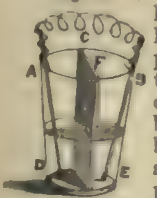


Fig. 64.

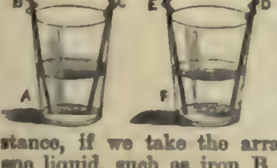


5th. *Separate Depositing Liquid with all the others.*—By connecting any one of the foregoing arrangements by means of wires with two separate pieces of metal of a similar kind immersed in a separate and suitable liquid (Fig. 64): for instance, if we take the arrangement of two metals in one liquid, such as iron B and copper C, in a solution of sulphate of copper A; or zinc B and silver C in dilute sulphuric acid A, and connect them by two separate wires, D and E, with two pieces of copper, D and E, immersed in a solution of sulphate of copper F contained in a separate vessel, the piece of copper E connected with the silver will dissolve, whilst the other piece D which is connected with the zinc will receive a deposit of copper; but if we substitute a solution of sulphate of zinc, freely acidulated with sulphuric acid, for the solution of sulphate of copper F, and two pieces of platina for the pieces of copper, the one piece of platina will not dissolve, nor the other receive a metallic deposit.

6th. *Separate Depositing Liquid with any other Source of Power.*—By connecting the pieces of metal in the separate depositing liquid with any other source of depositing power, such as a magneto-electric machine, cell, or battery.

2. In these arrangements, it will be observed that we have—1st, deposition by one metal and one liquid; 2nd, by two metals and one liquid; 3rd, by one metal and two liquids; 4th, by two metals and two liquids; 5th, by a separate depositing liquid and metals connected with either of these; and 6th, by a separate depositing liquid and metals connected with any other source of depositing power. These six classes, and their combinations, are capable of including all the known cases of electro-deposition.

3. Under the head of each of these classes will be mentioned a number of experiments with various metals and liquids; and it would be advisable for the student to try a few, as he proceeds, both of deposition and non-deposition of each class, in order to fix the facts more firmly in his memory, and give him a fuller comprehension of the principles.

4. *Depositing Arrangement No. 1.*—Deposition by one metal and one liquid (Fig. 65) takes place in the following instances:—

Hydrochlorate of Terchloride of Antimony.—In a solution of hydrochlorate of terchloride of antimony (the ordinary chloride of antimony, as prepared for pharmaceutical purposes), bismuth, zinc, tin, lead, brass, and German silver, become coated with antimony; whilst antimony, iron, nickel, copper, silver, gold, and platina do not become coated.

Fig. 65.

Chloride of Bismuth.—In a solution of acid hydrochlorate of bismuth oxide (chloride of bismuth), zinc, tin, lead, and iron, deposit the bismuth upon themselves; whilst antimony, bismuth, copper, brass, German silver, gold, and platina do not.

Sulphate, Chloride, Nitrate, or Acetate of Zinc.—In a solution of either sulphate, chloride, nitrate, or acetate of zinc, neither antimony, bismuth, zinc, tin, lead, iron, nickel, copper, brass, German silver, silver, gold, or platina become coated with zinc.

Protochloride of Tin.—In a solution of protochloride of tin, zinc and lead become tinned; whilst antimony, bismuth, tin, iron, nickel, copper, brass, German silver, silver, gold, and platina receive no deposit.

Hyponitrate, Nitrate, or Acetate of Lead.—In a solution of hyponitrate, nitrate, or acetate of lead, zinc receives a coating of lead; whilst antimony, bismuth, tin, lead, iron, nickel, copper, brass, German silver, silver, gold, and platina receive no deposit.

Ferrous Sulphate.—"Zinc," as Fischer says, "immersed in a perfectly neutral solution of ferrous sulphate (protosulphate of iron) contained in a stoppered bottle, throws down metallic iron, which is deposited partly on the zinc;" but in this solution neither antimony, bismuth, tin, lead, iron, nickel, copper, brass, German silver, silver, gold, or platina receive any metallic deposit.

Sulphate of Copper.—In a solution of sulphate of copper, zinc, tin, lead, and iron become coated with copper; whilst antimony, bismuth, nickel, copper, silver, gold, and platina do not.

Chloride of Copper.—In a solution of chloride of copper, bismuth, zinc, tin, lead, and iron receive a copper deposit: whilst antimony, nickel, copper, silver, gold, and platina do not.

Nitrate of Copper.—In a solution of nitrate of copper, zinc, tin, lead, and iron become coated; whilst antimony, bismuth, nickel, copper, silver, gold, and platina receive no deposit.

Dichloride of Copper.—With a solution of dichloride of copper in liquid ammonia, or of oxide of copper in a solution of sal-ammoniac, zinc receives a deposit; whilst antimony, bismuth, tin, lead, iron, nickel, copper, silver, gold, or platina do not.

Mercurial Salts.—Solutions of mercurial salts have their metal deposited by arsenic, antimony, bismuth, zinc, cadmium, tin, lead, iron, copper, and brass; also by the alloys of silver with zinc, tin, lead, or copper.

Nitrate of Mercury.—A solution of nitrate of mercury yields its metal to bismuth, zinc, cadmium, lead, iron, or copper, and, if acidulated with nitric acid, to antimony also; but not to silver, gold, or platina.

Acetate of Mercury.—Iron deposits mercury from a solution of acetate of mercury.

Silver Solutions.—The following metals—viz., manganese, arsenic, antimony, bismuth, zinc, cadmium, tin, lead, iron, copper, and mercury, deposit silver from its solutions in the metallic state; an aqueous solution of nitrate of silver yields its metal to manganese, arsenic, antimony, bismuth, zinc, tin, lead, iron, nickel, copper, brass, and German silver; but not to silver, gold, or platina. Lead and tin deposit the silver most quickly; then follow the other metals in this order—cadmium, zinc, copper, bismuth, antimony, arsenic, mercury. Arsenic deposits silver from the alcoholic solution of nitrate of silver; antimony receives a coating of silver either in the aqueous sulphate or alcoholic nitrate; bismuth deposits silver from the alcoholic nitrate, but not from the aqueous sulphate; zinc receives a silver deposit in the alcoholic nitrate; tin becomes silvered in the alcoholic nitrate, but more quickly in the aqueous sulphate; iron deposits silver from the sulphate of silver, but not from the alcoholic nitrate; copper deposits it from the aqueous sulphate or alcoholic nitrate; brass and the alloys of silver, with zinc, tin, or lead, deposit silver from silver solutions completely. In a solution of the double cyanide of silver and potassium (the ordinary plating liquid), zinc, lead, and copper become silvered; also brass and German silver, but more slowly; whilst antimony, bismuth, tin, iron, nickel, silver, gold, and platina do not.

Gold Solutions.—From an acid solution of terchloride of gold, most of the base metals, likewise mercury, silver, platina, and palladium deposit gold, generally in the metallic state, but not always; arsenic rapidly deposits gold from this solution; antimony, tellurium, and bismuth become gilded; zinc, cadmium, lead, iron, cobalt, mercury, silver, platina, and palladium deposit the gold; whilst titanium, tungsten, molybdenum, and chromium do not. In a solution of the double cyanide of gold and potassium, zinc quickly becomes gilded, and copper, brass, and German silver slowly; whilst antimony, bismuth, tin, lead, iron, nickel, silver, gold, and platina do not.

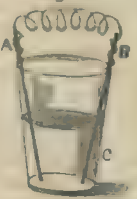
Bichloride of Platina.—Platina is deposited from a solution of its bichloride by arsenic, antimony, tellurium, bismuth, zinc, cadmium, tin, lead, iron, cobalt, nickel, copper, brass, German silver, mercury, and silver; but not by gold or platina.

5. *Observations upon Class of Instances, No.* 1.—In reviewing all these instances, we may make the following observations:—1st, that various metals, by mere immersion in solutions of other metals, at the ordinary temperature of the atmosphere, sometimes become coated with a deposit of metal, and sometimes not; 2nd, that no metal becomes coated by mere immersion in a solution of the same metal—for instance, zinc does not become coated with zinc in a solution of sulphate of zinc; copper with copper, in a solution of its sulphate, gold with gold in its chloride; 3rd, that the baser metals, especially zinc, cadmium, tin, lead, and iron, become coated more frequently than the noble metals, especially gold and platina; 4th, that solutions of base metals, especially of zinc and iron, yield their metal less frequently than those of the noble metals, especially those of gold and platina; 5th, that of all the ordinary metals mentioned in the foregoing instances, zinc deposits metal from the greatest number of solutions, and appears to have the strongest depositing power; 6th, that the coherent and adhesive deposits obtained, are, in all cases, exceedingly thin; and 7th, that frequently the deposited metal, whatever its kind may be, has the appearance of a black or dark-coloured powder on its surface, especially when it has been deposited very rapidly; but sometimes it exhibits its ordinary colour and appearance, especially if its outer portion be rubbed off.

6. To this mode of depositing belongs the process of tinning brass articles (wash tinning), by boiling them in water containing a salt of tin and bitartrate of potash; the process of silvering brass nails, buttons, hooks and eyes, buckles, &c., by rubbing them with any of the well-known silvering compositions moistened with water; also the water-gilding process, &c.

7. *Depositing Arrangement No.* 2.—*Deposition by Two Metals and One Liquid.*—The following instances belong to the class of deposition by two metals and one liquid, the two metals being either in mutual contact (touching each other either above or beneath the liquid), or connected together by a wire.

Fig. 66.



Chloride of Antimony.—If we immerse a piece of antimony A, in contact with a piece of zinc B, in a solution of the ordinary chloride of antimony C, it will receive a coating of antimony; or if we immerse a piece of platina in contact with a piece of tin in this liquid, it will receive a deposit of antimony; but if we immerse a piece of antimony in contact with a piece of platina, or a piece of platina in contact with a piece of silver in this liquid, it will receive no metallic deposit.

Chloride of Bismuth.—In a solution of chloride of bismuth, brass in contact with a piece of zinc, copper in contact with tin, or German silver with iron, receive a deposit of bismuth; but brass in contact with a piece of gold, gold in contact with silver, or German silver with platina, receive no deposit.

Sulphate, Chloride, or Nitrate of Zinc.—With a solution of either sulphate, chloride, or nitrate of zinc, no metal of any pair of metals selected from amongst the following, will receive a deposit of zinc: antimony, bismuth, zinc, tin, lead, iron, nickel, copper, mercury, silver, gold, platina, or palladium.

Protochloride of Tin.—With a solution of protochloride of tin, either antimony, tin, or copper, immersed in contact with zinc or lead, will receive a coating of tin; but antimony in contact with tin, tin with silver, copper with iron, or either gold or platina with copper, will not receive a deposit.

Hyponitrite of Lead.—With a solution of hyponitrite of lead, either tin, copper, or brass, in contact with a piece of zinc, will receive a deposit of lead; but tin in contact with copper, copper with lead, or brass with platina, receive no deposit.

Nitrate of Lead.—With a solution of nitrate of lead, either copper, brass, or silver, in contact with zinc, receive a coating of lead; but copper in contact with iron, brass with tin, or silver with copper, receive no such coating.

Protosulphate of Iron.—With a saturated solution of protosulphate of iron, platina in contact with zinc receives a deposit of iron; but in contact with copper it receives no metallic deposit.

Chloride of Nickel and Ammonia.—In a solution of the double chloride of nickel and ammonia, copper in contact with zinc receives a deposit of nickel; but in contact with silver it does not receive such a deposit.

Sulphate of Copper.—In a solution of sulphate of copper, brass in contact with zinc; or tin, German silver, silver, or platina, in contact with iron, receive a deposit of copper; whilst silver in contact with antimony, or platina in contact with brass, receive no deposit.

Oxide of Copper in Ammonia.—In a solution of oxide of copper in ammonia, platina in contact with zinc receives a deposit; but silver in contact with iron does not.

Nitrate of Mercury.—In a solution of nitrate of mercury, silver in contact with either zinc or iron, or platina in contact with copper, receive a metallic deposit; but platina in contact with silver does not.

Nitrate of Silver.—In a solution of nitrate of silver, gold in contact with zinc receives a deposit of silver; but in contact with platina it does not.

Bichloride of Platina.—In a solution of bichloride of platina, platina in contact with zinc becomes coated with platina; but in contact with gold it receives no such coating.

8. *Observations upon Class of Instances No. 2.*—The following general observations may be made upon the foregoing facts:—1st, that in some instances deposition does, and in others it does not, occur; 2nd, that no metal will cause another metal to be coated by this method, unless it can coat itself in the same liquid by simple immersion—for instance, zinc cannot coat itself with zinc in solutions of zinc, neither can it cause other metals to become coated with that metal in those solutions; copper cannot coat itself with zinc in a solution of sulphate of zinc, or with tin in a solution of chloride of tin; neither can it cause silver, gold, or any other metal, to become coated with zinc or tin, in those liquids; 3rd, that one of the two metals which receive a deposit by this method, derives its power of receiving the deposit by virtue of its contact with the other metal; 4th, that any metal which has the power of coating itself by simple immersion in a given liquid, can, by this method, cause other metals which do not coat themselves by simple immersion in that liquid to become coated—for instance, zinc, tin, and iron coat themselves with copper by simple immersion in a solution of sulphate of copper; and silver, gold, and platina do not; but if either of the former metals be connected with either of the latter, and the two are immersed together in that liquid, the latter metals, as well as the former, will become coated with copper; 5th, that base metals, and especially zinc, have generally the power of causing other metals to become coated by this method; whilst the noble metals, and especially gold and platina, rarely possess this power; 6th, that by this method, metal is deposited much more frequently from solutions of the noble metals, than from those of the base ones; and 7th, that thick deposits of metal may be obtained by this method, provided the action is continued sufficiently long, and the liquid properly renewed.

Fig. 67.

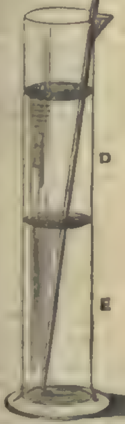


Fig. 68.

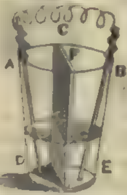


9. *Depositing Arrangement No. 3.—Deposition by One Metal and Two Liquids—Chloride of Antimony.*—The following instances belong to deposition by the immersion of one metal in two liquids, D and E (Fig. 68), separated by a porous diaphragm F, the metal being either in two pieces, connected together by a wire or wires C, or in one piece, and bent so as to dip into both liquids: the diaphragm may be dispensed with, as already explained (1), by pouring the lighter liquid carefully above the other, and placing the piece of metal vertically, as seen in Fig. 67. If two pieces of antimony, A and B, connected together by a wire or wires C, are immersed, one in dilute nitric acid D, and the other in a solution of chloride of antimony E, the piece in the dilute acid will dissolve, whilst that in the chloride solution will receive a metallic deposit.

Chloride of Bismuth.—If two pieces of antimony are immersed in the previous manner, one in hydrochloric acid, and the other in a solution of chloride of bismuth, that in the acid will dissolve, and the other receive a coating of bismuth.

Sulphate of Copper.—With antimony, in dilute hydrochloric acid on one side, and in a solution of sulphate of copper on the other, a deposit of copper is obtained.

Chloride of Bismuth.—With bismuth in hydrochloric acid on one side, and in a solution of chloride of bismuth on the other, a free deposit of bismuth is soon obtained.

Chloride of Zinc.—If a piece of zinc be bent so as to dip into dilute hydrochloric acid on one side, and into a neutral solution of chloride of zinc on the other, a free deposit of zinc will be found upon the end in the metallic solution after a period of twelve hours.

Solution of Acetate of Zinc.—With zinc in a solution of acetate of zinc on one side, and in dilute sulphuric acid on the other, that in the dilute acid will dissolve, whilst the other end will receive a metallic deposit.

Iron in Chloride of Antimony.—With iron in dilute sulphuric acid on one side, and in a solution of chloride of antimony on the other, the end in the metallic solution will receive a deposit of antimony, whilst that in the dilute acid will dissolve.

Iron in Sulphate of Zinc.—With iron in dilute sulphuric acid on one side, and in a solution of sulphate of zinc on the other, no deposit of zinc is obtained in twelve hours; similarly with iron, dilute sulphuric acid, and a solution of protosulphate of iron, no deposit occurs in twelve hours.

Tin in Chloride of Tin.—With tin in dilute hydrochloric acid on one side, and in a solution of chloride of tin on the other, a deposit of tin is obtained.

Zinc in Sulphate of Zinc.—With zinc in dilute sulphuric acid, and in a solution of sulphate of zinc, a free deposit of zinc occurs in twelve hours.

Bismuth in Nitrate of Bismuth.—With bismuth in dilute nitric acid, and in a solution of acid nitrate of bismuth, a thin deposit of bismuth is found in twelve hours.

Copper in Sulphate of Zinc.—With copper in dilute sulphuric or dilute nitric acid on one side, and in a solution of sulphate of zinc on the other, no deposit of zinc occurs in twelve hours.

Brass or Copper in Sulphate of Copper.—With brass or copper in dilute sulphuric acid on one side, and in a solution of sulphate of copper on the other, a deposit of copper is obtained in twelve hours; similarly with copper in dilute hydrochloric acid, and in a solution of chloride of copper, a metallic deposit occurs.

Silver in Plating Liquid.—With silver in either dilute sulphuric or dilute nitric acid on one side, and in a solution of sulphate of copper on the other, no deposit of copper takes place in twelve hours; but with silver in a solution of cyanide of potassium on one side, and in the double cyanide of potassium and silver on the other, a free deposit of silver takes place upon the end or piece in the latter solution.

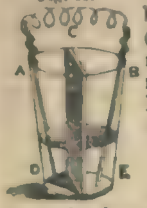
Platina in Nitrate of Copper.—With platina in aqua regia on one side, and in either a solution of nitrate of copper, the ordinary cyanide gilding solution, or a solution of bichloride of platina on the other, no deposit of copper, gold, or platina occurs.

10. *Observations on Class of Instances No. 3.*—1st, it appears, that in this class also we obtain negative as well as positive instances; 2nd, that by this arrangement, unlike the previous classes, almost any metal may cause the same metal to be deposited—for instance, zinc may deposit zinc, copper deposit copper, and silver deposit silver; 3rd, that by it even a noble metal may cause the deposition of a base metal, provided we have a suitable combination of liquids—for instance, if a piece of gold or silver be immersed in a strong solution of cyanide of potassium on one side, and in a solution of sulphate of copper or chloride of antimony on the other, the end in the free cyanide solution will dissolve, whilst that in the copper or antimony solution will receive a deposit; 4th, that the metal, or end which receives a deposit,

derives that power from its contact with the metal in the other liquid; 5th, that, as a general rule, base metals have a greater power of causing deposition by this method than the noble ones; 6th, that the noble metals are more readily and more often deposited than the base ones; and 7th, that we may produce thick and coherent deposits by this method.

11. *Depositing Arrangement No. 4.—Deposition by Two Metals and Two Liquids.*—The following instances belong to the class of deposition produced by the immersion of two metals, A and B (Fig. 69), in two liquids, D and E, the metals being in mutual contact, or connected together by a wire C, and the liquids separated by a porous partition F.

Fig. 69.



Zinc Depositing Antimony.—If a piece of antimony A be immersed in a solution of chloride of antimony D, and a piece of zinc B be immersed in dilute sulphuric acid E, and the two metals are connected together by a wire or wires C, a free deposit of antimony upon the metal A will take place in twelve hours.

Tin Depositing Zinc.—With tin in hydrochloric acid, and zinc in a neutral solution of sulphate of zinc, a deposit of zinc is obtained in the metallic solution.

Iron Depositing Antimony.—With iron in dilute hydrochloric acid, and antimony in chloride of antimony, a copious deposit of antimony takes place in twelve hours.

Copper Depositing Zinc.—With zinc in dilute sulphuric acid, and zinc in a solution of sulphate of zinc, a deposit of zinc occurs.

Zinc Depositing Copper.—With zinc in dilute sulphuric acid, and brass in a solution of sulphate of copper, copper is deposited.

Bismuth and Chloride of Antimony.—With bismuth in dilute hydrochloric acid, and antimony in chloride of antimony, no deposit of the latter takes place in twenty-four hours.

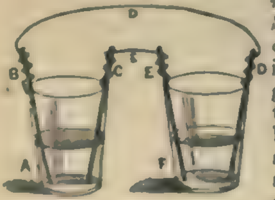
Iron and Chloride of Tin.—With iron in dilute hydrochloric acid, and tin in a solution of chloride of tin, no deposit of tin took place in eighteen hours.

Copper and Chloride of Antimony.—With copper in dilute hydrochloric acid, and antimony in chloride of antimony, or tin in chloride of tin, no deposit of antimony or tin took place in twenty hours.

12. *Observations upon Class of Instances No. 4.*—1st, it appears that negative as well as positive instances occur in this arrangement in common with the others; 2nd, that by using suitable metals and liquids, deposition may be effected more rapidly by this method than by the preceding ones; 3rd, that the metal which receives the deposit derives its power from its contact with the other metal; 4th, that base metals in strong acids have the greatest power of causing a deposit upon the other metals, and noble metals the least; 5th, that the noble metals are more readily deposited than the base ones; and 6th, that thick and coherent deposit may be obtained.

In all the above instances, instead of using one vessel divided into two parts by a porous diaphragm, it will be found convenient to put one of the liquids in an unglazed earthenware porous cell, and immerse the cell in the other liquid. (See vessel A, Fig. 71). In this case, either liquid may be in the outer vessel. This last arrangement (No. 4) is usually termed the "single cell" process.

Fig. 70.

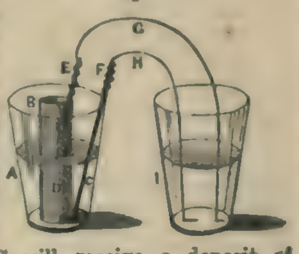


13. *Depositing Arrangement No. 5.—Deposition by Separate Liquid.*—The next class of instances are those in which either of the foregoing arrangements, except the first, may be connected by wires with two pieces of similar metal immersed in a separate liquid. For instance :—

1st. *With Two Metals and One Liquid* (Fig. 70).—If we take a vessel A, containing either dilute sulphuric acid or a solution of sulphate of copper, and immerse in it a piece of zinc B and copper C, with copper wires D and E attached to them, and either immerse the free ends of those wires in a separate solution of sulphate of copper F, or connect them with two pieces of copper immersed in that liquid, the piece of copper E in liquid F will dissolve, whilst the opposite piece D, connected with the zinc, will receive a deposit of copper.

2nd. *With One Metal and Two Liquids.*—If we take a vessel A (Fig. 71) containing a porous cell B, with a neutral solution of sulphate of zinc C in the outer vessel, and dilute sulphuric acid D in the inner, and immerse two pieces of zinc E and F, with copper wires G and H attached, into D and C respectively, and immerse the ends of those wires in a separate solution of sulphate of copper I, the end of the wire H will dissolve, whilst that of G will receive a deposit of metallic copper.

Fig. 71.

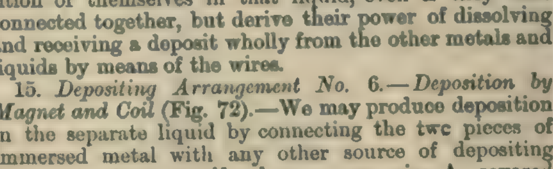


3rd. *With Two Metals and Two Liquids* ("single cell" arrangement, Fig. 71).—If we substitute a piece of copper for the piece of zinc F in the last-mentioned instance, and a solution of sulphate of copper for that of sulphate of zinc, similar effects will take place at the ends of the wires in the liquid I, except that the action will be much more rapid; but if in either of these three instances we use a solution of sulphate of zinc freely acidulated with sulphuric acid, instead of the solution of sulphate of copper I, and platina wires in place of the copper ones to be immersed, neither of the pieces of platina will dissolve or receive a metallic deposit.

14. *Remarks upon Class of Instances No. 5.*—In this class of instances, the method or arrangement differs from the three preceding ones, simply by the wires which connect the two pieces of metal being cut in two, and their free ends either immersed in a separate liquid, or connected with two pieces of metal dipping into that liquid. It is not necessary to have the depositing-vessel perfectly separated; it may even be attached to the same piece of apparatus, provided the liquid in it is perfectly separated from the other liquids and metals. The pieces of metal in the separate liquid possess no power of deposition of themselves in that liquid, even if they were connected together, but derive their power of dissolving and receiving a deposit wholly from the other metals and liquids by means of the wires.

15. *Depositing Arrangement No. 6.—Deposition by Magnet and Coil* (Fig. 72).—We may produce deposition in the separate liquid by connecting the two pieces of immersed metal with any other source of depositing power—for instance, if a long copper wire A, covered with silk or cotton, be coiled upon a large bar of pure soft iron B, and its ends C and D are immersed in a solution of sulphate of copper E, and the poles of a powerful horse-shoe magnet F are brought in contact very many times with the end of the bar, and every time before removing the magnet from the bar one of the ends of the wire be taken out of the liquid, and replaced before returning the magnet, one end of the copper will slightly dissolve, and the other receive a thin copper deposit; but if each of the ends be allowed to remain constantly in the liquid, no such effects will occur.

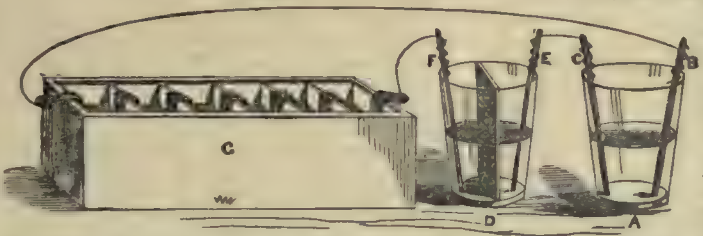
Fig. 72.



16. *Compound Depositing Arrangement No. 7.*—Any of the foregoing combinations of liquids and metals (except the first), or the magnetic arrangement, with or without

separate depositing liquids, may be connected together in a *series* of any number, and may include each of the arrangements in the same series, or include any number of depositing liquids, and deposition may be obtained either in the whole or in any portion of them at the same time: for instance, the vessel A (Fig. 73) contains a piece of zinc B, and copper C immersed in dilute sulphuric acid; vessel D contains zinc E, in dilute sulphuric acid, and copper F, in a solution of sulphate of copper; vessel G contains a series of separate depositing liquids, consisting of solutions of sulphate of copper, connected together by bent pieces of copper; the extreme pieces being attached to zinc B and copper F; here deposition takes place upon every alternate piece of copper throughout the whole series, except that in vessel A.

Fig. 73.



17. *General Observations.*—We may make the following general observations upon the whole of the foregoing facts:—1st, that negative as well as positive instances occur in all classes of facts of electro-deposition; 2nd, that almost any of the ordinary metals, both noble and base, may be deposited by each of the methods or arrangements described; 3rd, that the particular result of deposition or non-deposition occurring, appears to depend chiefly upon the particular combination of liquids and metals, their arrangement and connections; 4th, that the size or shape of the containing vessels, the bulk or depths of the liquids, the size, form, or position of the metals, appear to exercise little or no influence upon the result; 5th, that in all cases of deposition there is a difference in *kind*, either of the metal, of the liquid, or of both; 6th, that in all such cases a metal dissolves in a liquid; for instance, in Arrangement No. 1, with a piece of iron immersed in a solution of sulphate of copper, a portion of the iron is dissolved as the copper is deposited; in Arrangement No. 2, with iron and copper together in a solution of sulphate of copper, the iron dissolves and the copper receives a deposit; in Arrangement No. 3, with copper in dilute sulphuric acid, and in a solution of sulphate of copper, the copper in the acid dissolves, whilst that in the metallic solution receives a deposit; in Arrangement No. 4, with zinc in dilute sulphuric acid, and copper in sulphate of copper, the former dissolves, whilst the latter receives a deposit; in Arrangements Nos. 5 and 6, one piece of metal in the separate depositing liquid dissolves, whilst the other receives a metallic deposit, and the same with the compound Arrangement No. 7; 7th, that in Arrangements Nos. 1 and 2, the same piece of metal which dissolves also receives a metallic deposit; and in Arrangements 3, 4, 5, 6, and 7, the pieces of metal which receive a deposit do not dissolve; 8th, that, as a general rule, in all methods, and in all solutions, except alkaline metallic cyanides, zinc, among common metals, has the greatest, and platina the least power of producing deposition; 9th, that zinc generally deposits metals most rapidly from their solutions, and most frequently in the state of a dark-coloured or black powder; and 10th, that among solutions of the salts of ordinary metals, those of the salts of noble metals yield their metal most easily, and those of the base metals, zinc especially, with the greatest difficulty.

18. In looking over the foregoing instances, we also observe:—1st, that when several metals are used, they must either *touch* each other or be connected together by wires or other pieces of *metal;* 2nd, that when several liquids are used, they also must *touch* each other, either by means of a porous diaphragm, or otherwise; 3rd, that when a series of metals and liquids are used, they must together form a *complete circuit*, and all their points of contact be perfectly clean; 4th, that a separate depositing liquid possesses no power of deposition by itself, but derives its power by means of the wires from the other arrangements with which it is connected; and 5th, that the length of the connecting wire, if not great, has no influence on the result. These observations have led us to conclude that deposition is caused by some *force* which is generated in some part of the apparatus, and circulates through the liquids, metals, and wires, which compose the circuit.

19. *Principles.—Conditions of Electro-Deposition.*—From the simple *facts* of electro-deposition, and the general observations made upon them, we proceed to consider the *causes* of deposition, and the conditions or circumstances under which deposition occurs, in the following order:—

1st. *The Chemical Conditions.*—If we immerse a clean iron wire in a solution of nitrate of mercury, it receives a deposit of that metal; but if we immerse it in perfectly dry metallic mercury, it receives no deposit, because in the former case the necessary chemical conditions of deposition are present, whilst in the latter case they are absent.

2nd. *The Electrical Conditions.*—If we connect together a piece of iron and a piece of copper, by means of a metal wire, and immerse them in a solution of sulphate of copper, the copper will receive a metallic deposit; but if we connect them together by a cord of gutta-percha, or rod of glass, no deposit will take place, because, in the former case, all the electrical conditions are present, whilst in the latter case, one of them—viz., a complete conducting circuit, is absent.

3rd. *The Thermal Conditions* remain almost unknown.

4th. *The Mechanical Conditions.*—If a piece of iron be immersed in a solution of sulphate of copper, it receives a copper deposit; but if a piece of platina be so immersed it receives no such deposit, because, for one reason, in the former instance the mechanical conditions of attraction and repulsion at the dissolving and depositing surfaces are present, but in the latter they are absent.

5th. *The Mathematical Conditions.*—If we immerse two pieces of carbon in fused *proto*-chloride of tin, and connect them with a voltaic battery, tin will be deposited: but if we immerse them in fused *bi*-chloride of tin, no deposition will occur, because, in the first instance, all the mathematical conditions are present; the fluid salt contains *one* atom of chlorine for each atom of tin; whilst in the latter case one of them is absent, the salt contains *two* atoms of chlorine to one atom of tin; and, according to Faraday's law, "only those substances of the first order are directly decomposable which contain one atom of one of their elements for each atom of the other."

These several heads are capable of including all the known circumstances or conditions under which deposition occurs; and under each of them will be given a few instances, both of deposition and non-deposition, to illustrate the principle. It would be advisable for the reader to try for himself most of the experiments given, in order to fix the principles firmly in his memory.

20. *Chemical Conditions of Deposition.*—The first chemical condition to be observed is, that in every case of deposition, the depositing liquid contains acid and basic elements—namely, a salt, the acid of which is to dissolve or combine with one metal, and its metal or base to be deposited upon the other.

1st. *Deposition by One Metal and One Liquid.*—With the first class of facts, if we immerse a piece of clean iron in a solution of nitrate of mercury, it will receive a deposit of that metal; but if we immerse it in mercury alone, it will receive no deposit: in the first instance an acid as well as a basic substance was present, and deposition took place; but in the second instance the metal or base alone was present, and no deposition occurred.

2nd. *With Two Metals and One Liquid.*—If zinc and platina are immersed in mutual contact in a solution of nitrate of mercury, the platina will receive a metallic deposit; but if they are immersed in pure dry mercury, no deposit will occur.

3rd. *With One Metal and Two Liquids.*—If we immerse one end of a platina wire in a strong solution of cyanide of potassium, and its other end in a solution of nitrate of mercury, the two liquids being in mutual contact by means of a porous partition, the end in the metallic solution will soon receive a deposit of mercury; but if perfectly dry mercury be substituted for the nitrate solution, no such deposit will occur.

4th. *With Two Metals and Two Liquids.*—If we immerse zinc in dilute sulphuric acid, and platina in a solution of nitrate of mercury, the two liquids being separated by a porous partition, and the metals connected together by a wire, the platina will quickly receive a deposit of mercury; but with dry mercury instead of the metallic solution, the platina will not receive a deposit.

5th. *With a Separate Depositing Liquid.*—If we take two pieces of platina wire, connect them, as already described (13), with either of the foregoing Arrangements, or with a magnet and coil (15), and immerse their free ends in a solution of nitrate of mercury, one of the wires will receive a deposit of mercury; but if the separate liquid consist only of dry mercury, no deposit will be obtained.

It is evident from these facts, that in every case where deposition occurs, the depositing liquid contains both acid and basic substances, and that without the presence of both no deposition will take place.

21. *Degrees of Chemical Affinity of Metals and Liquids.*—At the present point it is necessary to mention a few instances of the different degrees of chemical affinity manifested by different metals and liquids, that the reader may be able to understand their general chemical relations in electro-deposition more clearly.

1st. If we immerse a piece of potassium in almost any liquid, very violent chemical action takes place, which is stronger in mineral and vegetable acids than in water or organic liquids; if we place a small piece of it upon water, violent chemical action occurs, the water is decomposed, heat is produced, gas is evolved which takes fire, the metal melts and rolls about on the surface of the water, oxidates and dissolves.

2nd. If we immerse a piece of zinc in any of the strong mineral acids (sulphuric, hydrochloric, hydrofluoric, or nitric acids), strong chemical action takes place, gas is freely evolved, and the metal oxidates and dissolves; with solutions of the ordinary vegetable acids, *i.e.*, oxalic, tartaric, citric, formic, and acetic acids, the same effects occur in a much weaker degree; but with pure water there is no visible decomposition, no gas evolved, nor any perceptible chemical action. These instances show that potassium has a much stronger affinity for water or its oxygen than zinc, and that both potassium and zinc have a stronger affinity for acids, especially mineral ones, than for water.

3rd. If we immerse a piece of zinc successively in each of the ordinary mineral and vegetable acids diluted with water, it will be quickly dissolved, with evolution of hydrogen gas in nearly all of them; but if we immerse a piece of copper in those liquids, it will be quickly dissolved in only one of them—viz., nitric acid; and from this we conclude that copper has generally a much weaker affinity for acids than zinc.

4th. If we immerse either gold or platina in any of the strong mineral or vegetable acids, or even in cold aqua regia, it will be quite unaffected in all of them; whilst copper would be rapidly acted upon by nitric acid or by aqua regia, and slowly by several of the others, thereby showing that the affinity of gold or platina for acids, is generally much weaker than that of copper.

From the foregoing, and many other instances that might be mentioned, we conclude that the general order of affinity of the metals for acids occurs in the following order—namely, potassium, zinc, copper, gold, and platina. Hydrocyanic acid and cyanogen appear to differ in one respect, in their chemical relations towards ordinary metals, from oxygen, chlorine, and the ordinary mineral and vegetable acids, in having a much stronger affinity for noble metals, and a weaker for base metals: this is probably one of the chief reasons for the extensive adoption of cyanogen compounds in electro-deposition. Those compounds are highly suitable for the deposition of noble metals, because of the great affinity of cyanogen for them; but not, as some persons assert, for the deposition of many of the base metals, on account of a comparatively weak affinity for them.

22. Potassium is an *alkali* metal; zinc, cadmium, tin, lead, iron, cobalt, nickel, and copper, are *base* metals; and mercury, silver, gold, platina, palladium, &c., are *noble* metals; and of these three classes, the alkaline metals possess the strongest affinity for acids, base metals intermediate, and noble metals the least. The same order prevails in their degrees of depositing power; potassium and the alkaline metals generally deposit nearly all others from their solutions; zinc, and the base metals generally, deposit a smaller number; and gold, platina, and the other noble metals deposit a very few from their solutions. Thus we perceive that those metals which have the strongest chemical affinity for acids, possess the greatest depositing power; and those which have the least affinity for acids, have also the least depositing power.

23. *Difference of Chemical Affinity necessary to Deposition.*—The second chemical condition which we have to observe upon is, that, in every case of *deposition*, there is a *difference* of chemical affinity at the dissolving and receiving surfaces for the different elements of the liquid, and that the dissolving metal has a stronger affinity for the acid elements of the liquid than either the metal in solution or the receiving metal. For instance—

1st. *With One Metal and One Liquid.*—If we immerse a piece of iron in a solution of sulphate of copper, a deposit takes place upon it; but if we immerse a piece of platina in the liquid, it receives no deposit: in the first case, the iron having a stronger affinity for the sulphuric acid of the salt than copper, combines with it and dissolves, and the copper thereby set free from the acid is deposited upon the iron; whilst in the second case, platina having a much weaker affinity for the acid than the copper, cannot separate the acid and copper, and therefore cannot cause deposition.

2nd. *With Two Metals and One Liquid.*—If we immerse copper and iron in mutual contact, in a solution of sulphate of copper, the iron dissolves, and deposition of copper takes place upon both metals; but if we immerse copper and platina in mutual contact in this solution, no deposition will occur. In the first instance, the iron possessing a stronger chemical affinity for sulphuric acid than the copper, combines with it, and sets the copper free; by this action, a current of depositing force is generated, which circulates through the iron, liquid, and copper, at their points of contact, and causes the metal of the liquid to be deposited upon the piece of copper; but in the second case, neither the copper nor platina possessing a stronger affinity for the acid of the salt than its associated metal, there is no copper set free, no current of depositing force generated, and consequently no deposition takes place.

3rd. *With One Metal and Two Liquids.*—If we immerse one end of a piece of copper in dilute sulphuric acid, and the other in a solution of sulphate of copper, the two liquids touching each other, copper will be deposited upon the end immersed in the metallic solution, whilst the other end will combine with the acid and dissolve; but if a piece of platina or gold be substituted for the copper, neither of its ends will dissolve or receive a metallic deposit: in the first instance, the dilute sulphuric acid, having a stronger affinity for copper than a solution of sulphate of copper, combines with it, causes it to dissolve, develops a current of depositing force which circulates through the metals and liquids, and a deposit of copper is produced; whilst in the second instance, the platina or gold having a weaker affinity for the acid of one liquid than copper for the acid of the other liquid, cannot separate the copper, or cause deposition.

4th. *With Two Metals and Two Liquids.*—If we immerse a piece of silver in a strong solution of cyanide of potassium, and a piece of copper in a solution of the double cyanide of copper and potassium, the liquids being separated by a porous partition, and the metals connected by a wire, the silver will dissolve, and the copper receive a metallic deposit; but if a piece of iron be substituted for the silver, no deposit will occur. In the first instance, the one solution has a stronger affinity for the silver than the other has for the copper—consequently the former is dissolved, a current or depositing force is generated, and copper deposited; but in the second case, the one liquid has a weaker affinity for iron than the other has for copper, and therefore no iron is dissolved, no depositing force generated, and no copper deposited.

5th. *With a Separate Depositing Liquid connected with any Source of Depositing Power.*—If we connect two pieces of silver with any of those sources of power, and immerse them in a solution of the double cyanide of silver and potassium, one piece will quickly dissolve, and the other receive a deposit of silver; but if pieces of iron are substituted for those of silver, neither will dissolve or receive a metallic deposit.

In every case where a separate depositing liquid is used, the two pieces of metal immersed in it have a *difference* of chemical affinity imparted to them by virtue of their connection with some arrangement which develops depositing force; and this difference of affinity is manifested most when the liquid has a strong affinity for the immersed metal, and least when it has a weak affinity for that metal: so in the first of the two immediately preceding instances, the liquid having a strong affinity for silver, allows this difference of affinity to be freely exercised at the immersed surfaces of the two pieces of metal, and consequently one dissolves, and the other receives a deposit; but in the second of these instances, the liquid having a very weak affinity for iron, does not admit of the exercise of this difference of affinity, and hence neither piece dissolves or receives a deposit. From these instances it is manifest, that whenever deposition occurs, there is a difference of chemical affinity between the dissolving and receiving surfaces for the different elements of the liquid; that the dissolving metal has a stronger affinity for the acid elements than the receiving one; and without this condition no deposition will occur.

24. It must be mentioned, also, that the metals which have the greatest difference in their degrees of affinity for acids, are those which evolve the greatest strength of depositing power. For instance—

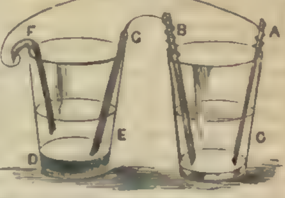
1st. *With One Metal and One Liquid.*—If we immerse a piece of silver in a solution of terchloride of gold, it slowly becomes gilded; but if we immerse a piece of zinc in it, gold is almost instantaneously deposited; because, in the former case, the difference of affinity between gold and the immersed metal for the acid of the liquid is very much smaller than in the latter case.

2nd. *With Two Metals and One Liquid.*—If we immerse a piece of platina and a piece of copper, in mutual contact, in a solution of nitrate of silver, the platina will become silvered, but much more slowly than if iron or zinc were used in place of the copper, because there is a greater difference of affinity between platina and iron or zinc for the acid of the liquid, than between platina and copper; or, if we immerse a piece of zinc and a piece of platina or platinised silver in dilute sulphuric acid, and connect them separately with two pieces of copper immersed in a separate solution of sulphate of copper, copper will be dissolved and deposited in the separate liquid more rapidly than if we used zinc and copper in place of zinc and platina, and much more rapidly than if we used iron and copper, because the difference of affinity between zinc, platina, or platinised silver for dilute sulphuric acid, is more than zinc and copper for that liquid, and much more than between iron and copper.

3rd. *With Two Metals and Two Liquids.*—If we immerse a piece of zinc in dilute sulphuric acid, and a piece of copper in a solution of sulphate of copper, the two liquids touching each other, and the two metals connected with two pieces of copper in a separate solution of sulphate of copper, the amount of metal dissolved and deposited in a given time in the separate liquid, will be much smaller than if we used zinc in dilute sulphuric acid, and platina in strong nitric acid; because the difference of affinity between the two metals in the two liquids, in the first instance, is less than in the second instance.

25. *Acid and Basic Affinities necessary.*—Chemical affinity differs not only in degree; but also in kind; basic substances, such as metals, alkalies, alkaloids, and most metallic oxides, have a great tendency to combine with acids; whilst oxygen, sulphur, phosphorus, chlorine, iodine, bromine, fluorine, mineral and vegetable acids, and some metallic oxides, tend to combine with bases. In a similar manner, the difference of affinity between the dissolving and receiving surfaces in electro-deposition is not wholly one of degree, but is also one of kind: the dissolving metal, in a separate depositing liquid (13), acquires, by virtue of its connection with some source of depositing power, an affinity for the *acid* elements of the liquid; whilst the receiving metal acquires, by the same means, an affinity of an opposite kind: for instance (Fig. 74), if a piece of platina A, and a piece of zinc B, are immersed in dilute sulphuric acid C, some mercury D placed at the bottom of a separate solution of protosulphate of iron E, a piece of iron F immersed in this liquid and connected by a wire with the platina, and the mercury connected by an iron or platina wire G, which is prevented from touching the liquid by a tube of glass or gutta-percha, the immersed piece of iron will exercise one kind of affinity, combine with the acid of the dissolved salt, and form a definite chemical compound (protosulphate of iron), containing one equivalent of iron and one equivalent of sulphuric acid; while the mercury will exercise an opposite kind of affinity, and combine with the metal or base of the salt, forming likewise a definite chemical compound (Fe Hg), containing one equivalent of iron and one of mercury. If a solution of sulphate of copper be substituted for that of sulphate of iron, and a piece of copper for the piece of iron, a similar definite compound of copper and sulphuric acid will be formed at the dissolving plate, and of copper and mercury (Cu Hg) at the receiving metal.

Fig. 74.



These experiments prove, in a most satisfactory manner, that, in the act of deposition, the surface of the dissolving metal possesses one kind of affinity by virtue of which it tends to attract *acid* substances, and combine with them in definite proportions; and the surface of the receiving metal possesses an opposite kind of affinity, by virtue of which it tends to attract and combine with *basic* substances, also in definite proportions. Mercury is the only metal which has been observed to manifest this definite affinity at the receiving surface, probably because it is the only metal fluid at ordinary temperatures, fluidity being an essential condition of such affinity; but it is likely that other metals would also manifest this tendency, if kept in a melted state in contact with suitable fused salts, and properly acted upon by depositing force.

26. *Fluidity essential to Electro-Deposition.*—The affinities of electro-deposition, like those of ordinary chemical action, require, generally speaking, one at least of the combining bodies to be in the liquid state; and they act, like them, wholly at insensible distances, being confined in their exercise to the immediate surfaces of mutual contact in the opposed substances. The compound formed at those surfaces becomes diffused through the fluid masses by capillary attraction and mechanical

mixture. This affords a reasonable explanation why fluidity of the receiving metal is essential to the formation of definite compounds at its surface, as well as why fluidity of the metallic salt is essential to its decomposition, and for the formation of definite compounds at the dissolving surface. If chemical action took place at sensible and considerable distances, *i.e.*, throughout the whole mass of the opposed fluid bodies, combination would probably be in all cases violent and instantaneous; and if fluidity were not essential to combination, the substances deposited upon the receiving surface would probably, in most cases, enter into the mass of the receiving metal, and combine with it.

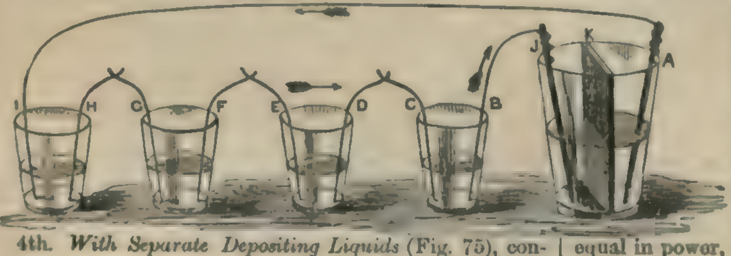
27. *Alternation and Circulation of Chemical Affinities necessary.*—The next chemical condition to be mentioned is, that in every case of deposition, the surfaces at which the acid and basic affinities are manifested, *alternate* with each other in the circuit, and that the acid affinity *circulates* one way, while the basic affinity *circulates* in the opposite direction. For instance—

1st. *With One Metal and One Liquid.*—If we immerse a piece of copper in a solution of double cyanide of silver and potassium, it becomes silvered; but if we immerse a piece of iron therein, it receives no deposit. In the first of these instances, it is considered that, immediately upon the immersion of the metal, the superior affinity of copper for cyanogen over that of silver, causes it to combine with that compound, and sets the silver free; at the same time, an immense number of minute currents of depositing force or chemical affinity are developed all over the immersed surface of the piece of copper, leaving it at innumerable minute points, passing a very small distance into the liquid, and re-entering the copper at numberless other points; and thus the affinities circulate, the copper dissolves, and receives a deposit simultaneously. In each of these atomic circuits, as they are termed, acid affinity is exercised where the depositing force leaves the metal, and basic affinity where it re-enters it; but in the second instance, where iron is used, there is no circulation of those affinities, no dissolving of metal at one point, or deposition of it at another.

2nd. *With Two Metals and One Liquid.*—If we immerse a piece of iron and a piece of copper, in mutual contact, in a solution of sulphate of copper, a deposit of copper will take place upon the iron and upon the copper; but if we immerse a piece of gold in place of the iron, no deposit will occur upon either. In the first of these instances, in addition to the circulation of atomic currents of affinity all over the immersed surface of the iron, as already explained, and which causes it to dissolve and receive a deposit, there are separate and distinct currents of the same force circulating through the liquid; and the two metals, by their points of mutual contact, cause the surface of the iron to combine with the acid, and that of the copper to receive a metallic deposit; but in the second case there is no circulation of affinities, and no solution of the gold, or deposition of the copper.

3rd. *With One Metal and Two Liquids.*—If we immerse two pieces of silver, one in a solution of cyanide of potassium, and the other in a solution of double cyanide of silver and potassium, the two pieces being connected together by a wire, and the liquids being divided only by a porous partition, chemical affinities will circulate by the metals, wire, and liquids, and silver will be dissolved and deposited; but if we substitute pieces of iron for the pieces of silver, there will be no circulation of affinities and no deposition.

Fig. 75.



4th. *With Separate Depositing Liquids* (Fig. 75), consisting of solutions of sulphate of copper, with separate pairs of copper wires C D, E F, G H, immersed in them, and with end pieces of copper B and I, B being connected with a piece of zinc J immersed in dilute sulphuric acid, and I connected with a piece of copper A immersed in a solution of sulphate of copper, the two liquids being separated by a porous diaphragm K, chemical affinities will circulate in opposite directions through the whole of the circuit, every alternate piece of immersed metal, J, I, G, E, and C, will exercise one kind of affinity and dissolve, and every other alternate piece, A, B, D, F, and H, will exercise an opposite kind of affinity, and receive a deposit of copper. If in either of the foregoing instances, where deposition occurs, we break the continuity of the circuit, either by separating the metals from each other at their points of contact, lifting them out of the liquid, or by cutting through the connecting wires, no deposition will occur; but if we immerse the free ends of the divided wire in a suitable liquid, such as a solution of sulphate of copper, if the wires are of copper, deposition will immediately recommence throughout the circuit.

28. A consideration of such facts as these, leads us to conclude that the process which causes every alternate metal in a series to combine with *acids* and dissolve, and every other alternate metal in the circuit either to combine with bases, or receive a deposit, is of a chemical character, and occurs in opposite directions through the circuit, which has led to the application of the term "current affinity," to designate the depositing force, when viewed only in a *chemical* aspect.

29. Two or any other *even* number of vessels containing combinations of liquids and metals, each similar, and capable of generating current affinity, may be so arranged in a complete conducting circuit, that no current affinity will circulate or deposition occur: for instance, if we take two separate vessels A and B (Fig. 76), each containing dilute sulphuric acid, and a separate piece of zinc Z, and silver (S), and connect them together thus, zinc-silver silver-zinc, no depositing power will be manifested if we immerse the free ends of their copper wires C C in a separate solution of sulphate of copper D; but if they are connected thus, zinc-silver zinc-silver (Fig. 77), and the copper wires immersed as before, current affinity will circulate, and deposition will proceed in the separate liquid. In the first of these cases the affinities set in motion by the metals and liquid in the vessel A are opposite in direction to those generated in vessel B, and the two arrangements, being equal in power, exactly neutralise each other, preventing

Fig. 76.

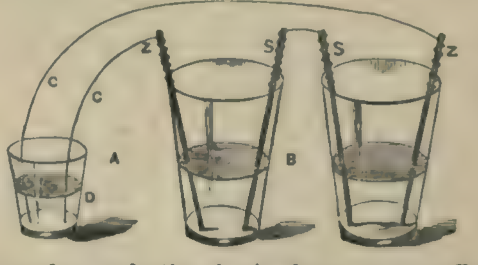


Fig. 77.

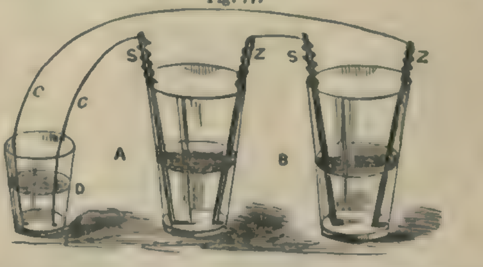


the currents of affinity and their effects; but, in the second case, the direction of the affinities evolved by the vessel A coincide with that of those from vessel B, the currents circulate, and deposition is effected. In the case of an unequal portion of the metals of a series being connected in the opposite way, those which are wrongly connected will neutralise and be neutralised by an equal number of the remainder, provided that all the pairs of metals and the liquids are similar: for instance, if three out of twelve are wrongly connected, they will neutralise the power of three more, and only the remaining six will act in the desired direction.

30. During the act of deposition, a salt is generally formed at the dissolving surface by the union of the metal with the acid elements of the liquid, which is dissolved in the liquid; at the same time the acid, which combines with the dissolving surface, is generally set free at the receiving surface by the deposition of the metal. For instance—

1st. *With One Metal and One Liquid.*—When iron coats itself with mercury by simple immersion in a solution of nitrate of mercury, nitrate of iron is formed by the union of the iron with the nitric acid of the nitrate of mercury, and nitric acid is at the same time set free by the deposition of the mercury.

2nd. *With Two Metals and One Liquid.*—When copper receives a deposit of copper by immersion, in contact with a piece of iron in a solution of sulphate of copper, sulphate of iron is formed at the immersed surface of the iron, by the union of the sulphuric acid of the sulphate copper salt, with the iron; at the same time sulphuric acid is set free at the copper surface by the deposition of the copper.

3rd. *With One Metal and Two Liquids.*—When copper receives a deposit of copper in a solution of sulphate of copper, by connection with another piece of copper immersed in dilute sulphuric acid, the two liquids being separated by means of a porous partition or otherwise, sulphate of copper is formed at the surface of the metal in the dilute acid, by the union of the copper with the acid, and, at the same time, sulphuric acid is set free at the surface of the other piece by the deposition of the copper.

4th. *Silver.*—When silver or any other metal receives a coating of silver in a solution of double cyanide of silver and potassium, by connection with a piece of zinc in dilute sulphuric acid, the two liquids being separated by a porous diaphragm, sulphate of zinc is formed at the surface of the zinc, by the union of the acid and zinc, and cyanogen (a substance of an acid character) is at the same time set free at the receiving surface, by the deposition of the silver.

5th. *With a Separate Depositing Liquid*, connected with any source of current affinity: for instance, when two silver plates, immersed in a solution of the double cyanide of silver and potassium, are connected by wires with a piece of zinc, and a piece of copper immersed in dilute sulphuric acid in a separate vessel, cyanide of silver is formed at the surface of one of the pieces of silver by the union of that metal with the cyanogen of the liquid; and, at the same time, either cyanogen or hydro-cyanic acid is set free at the surface of the other piece by the deposition of the silver.

31. *Proper Proportion of Free Acid in the Depositing Liquid.*—If a solution contain a large excess of uncombined acid, metallic deposition will not always occur: for instance, if two pieces of zinc are immersed in a neutral solution of sulphate of zinc, and connected by wires with another piece of zinc, and a piece of silver immersed in dilute sulphuric acid, in a separate vessel, one piece of zinc will dissolve, and the other receive a deposit of metal; but if a rather large quantity of sulphuric acid be added to the depositing liquid, no deposit of zinc will occur. In the same manner, if we connect two pieces of silver, immersed in a strong solution of cyanide of potassium, with the zinc and silver in dilute sulphuric acid, as just described, one of the pieces of silver will combine with the cyanogen of the cyanide of potassium, and form cyanide of silver, which will combine with a portion of the remaining cyanide and then dissolve; but the other piece of silver will not receive a deposit of silver, until the remaining uncombined cyanide of potassium has decreased to a certain proportion by the working of the process. If, on the other hand, a depositing solution contain no *free* combining substance, deposition will either proceed very slowly, or be entirely stopped, in consequence of an insoluble salt being formed upon the surface of the dissolving metal, which will impede the action: for instance, when two silver plates, immersed in a solution of double cyanide of silver and potassium, are connected with some source of depositing power, one of the plates will receive a deposit of silver, whilst the other will gradually become covered with a white layer of insoluble cyanide of silver, which eventually stops deposition.

32. *Necessity of a Proper Proportion of Water.*—If a depositing solution be diluted with water to a very large extent, deposition will progress very slowly; but if, on the other hand, it contain insufficient water, crystals of metallic salts will collect upon the dissolving metal, and gradually stop the action: for instance, if two pieces of copper, immersed in a *saturated* solution of sulphate of copper containing free acid are connected with a piece of zinc, and a piece of silver immersed in dilute sulphuric acid in a separate vessel, one piece will receive a deposit of copper, whilst the other will slowly dissolve and gradually become covered with crystals of sulphate of copper, first at its lower part and then at the edges, which will gradually stop the action.

33. All the foregoing facts prove that chemical affinity plays a very important part in the phenomena of electro-deposition.

34. *Electrical Conditions of Deposition—Positive and Negative Substances necessary.*—The first electrical condition to be observed is, that in every case of deposition, the liquid contains both substances of an electro-positive and of an electro-negative character; metals and alkalies are electro-positive, and metalloids (oxygen, sulphur, chlorine, iodine, bromine, &c.) and acids are electro-negative; cyanogen is also electro-negative.*

1st. *With One Metal and One Liquid.*—In the first instance, if we immerse a piece of copper in a solution of nitrate of mercury, deposition occurs, mercury being thrown down; but if we immerse it in dry mercury, there is no deposition: in the former case the liquid contains both electro-positive mercury and negative nitric acid, but in the latter case it only contains the positive mercury.

2nd. *With Two Metals and One Liquid.*—Immerse zinc and platina in mutual contact in a solution of nitrate of mercury, the platina will receive a deposit; but if we immerse them in dry mercury, it will receive no deposit.

3rd. *With One Metal and Two Liquids.*—If one end of a platina wire be immersed in a solution of cyanide of potassium, and the other end in a solution of nitrate of mercury, the two liquids being separated by a porous partition, the end in the mercurial solution will receive a metallic deposit; but if dry mercury be substituted for the nitrate solution, no deposition will occur.

4th. *With Two Metals and Two Liquids.*—If we immerse zinc in dilute sulphuric acid, and platina in a solution of nitrate of mercury, the metals touching each other, and the liquids separated by a porous partition, the platina will receive a mercurial deposit; but when dry mercury is substituted for the nitrate solution, it will receive no deposit.

5th. *With a Separate Depositing Liquid.*—If we immerse two platina wires in a solution of nitrate of mercury, and connect them with any source of depositing power, one of the wires will receive a metallic deposit; but if we use dry mercury instead of the nitrate solution, there will be no deposit.

These and many other instances prove, that unless the depositing liquid contain both electro-positive and electro-negative substances, no deposition will occur.

35. *Electric Polarity of the Dissolving and Receiving*

---

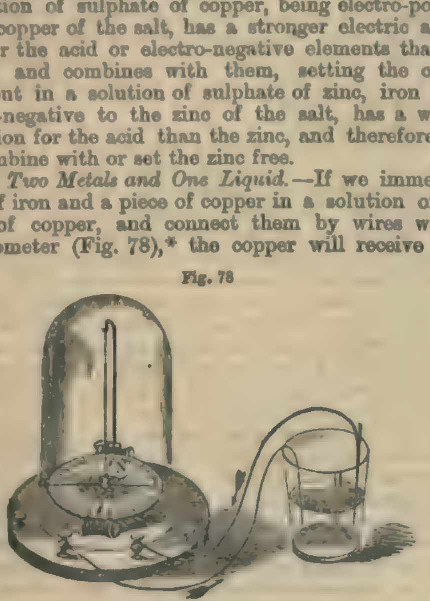
* See *ante*, p. 194.

Metals.—The second electrical condition to be observed is, that in every case of deposition there is an electrical difference between the dissolving and receiving metals, and that the former is always electro-positive, the latter being electro-negative, relatively to each other; the dissolving metal, consequently, has the strongest electrical attraction for the electro-negative or acid elements of the liquid, and the receiving metal has the strongest electrical attraction for the electro-positive or metallic elements. For instance—

1st. *With One Metal and One Liquid.*—Iron placed in a solution of sulphate of copper, being electro-positive to the copper of the salt, has a stronger electric attraction for the acid or electro-negative elements than the copper, and combines with them, setting the copper free; but in a solution of sulphate of zinc, iron being electro-negative to the zinc of the salt, has a weaker attraction for the acid than the zinc, and therefore does not combine with or set the zinc free.

2nd. *Two Metals and One Liquid.*—If we immerse a piece of iron and a piece of copper in a solution of sulphate of copper, and connect them by wires with a galvanometer (Fig. 78),* the copper will receive a deposit, and the needle N of the instrument will be strongly deflected in such a direction as to indicate that the iron is positive, and the copper negative; but if a piece of iron and a piece of zinc are immersed in a solution of sulphate of zinc, and connected with the instrument, no deposit will take place upon either metal, and scarcely any deflection of the needles will be produced.

Fig. 78



3rd. *With One Metal and Two Liquids.*—If one piece of copper be immersed in dilute sulphuric acid, and another in a neutral solution of sulphate of copper, the two liquids being separated by a porous partition, and the pieces of copper connected by wires with the galvanometer, deposition will take place upon the piece of copper in the metallic solution, and the instrument will indicate, by the direction of the deflection of its needles, that the dissolving piece of metal is positive, and the receiving piece negative; but if we substitute two pieces of platina for the pieces of copper, no deposition of copper will occur, and scarcely any difference of electric condition between the two pieces of metal will be indicated by the galvanometer.

4th. *With Two Metals and Two Liquids.*—If a piece of zinc be immersed in dilute sulphuric acid, and a piece of copper in a solution of sulphate of copper, the two liquids being separated by a porous partition, and the metals connected with the galvanometer, deposition will take place freely upon the copper, and the needles of the instrument will be powerfully deflected, indicating, by the amount and direction of their movement, the zinc to be strongly positive and the copper negative; but if a piece of platina be substituted for the zinc, there will be no deposition, and scarcely any deflection of the needle.

5th. *With a Separate Depositing Liquid.*—If we immerse two pieces of silver in a solution of the double cyanide of silver and potassium, and connect them with any source of depositing power, interposing a galvanometer in the circuit, deposition of silver will occur, and the needles will be strongly deflected in such a direction as to indicate the dissolving piece of silver to be positive, and the receiving piece negative; but if we substitute two pieces of iron for the pieces of silver, there will be scarcely any deposition of silver, and very little deflection of the needle, the receiving piece being feebly negative. From these and many other similar cases, we conclude, that in every case where deposition occurs, the dissolving metal is electro-positive, and the receiving metal electro-negative, and that the former has the strongest electric attraction for the negative elements of the liquid, and the latter for the basic or metallic element. In all electric phenomena, positive substances repel positive and attract negative, and negative substances repel negative and attract positive.†

36. *Alternation and Circulation of Electro-Polarities necessary.*—The third electric condition is, that in every case of deposition, the positive and negative surfaces, or metals, *alternate* with each other in the circuit, and electric forces *circulate* through the circuit. For instance—

1st. *With One Metal and One Liquid.*—When a piece of iron is immersed in a solution of sulphate of copper, innumerable minute electric currents are generated upon the surface of the metal, and circulate to a very minute depth within the opposed surface of the liquid; while the positive electricity, passing out of innumerable points of the iron into the solution, causes it to dissolve—pass through the solution, re-enter the iron at innumerable other points, and deposit the copper; but when a piece of gold is immersed in this solution, there are no currents of electricity generated, and the gold is neither dissolved nor does it receive a deposit.

2nd. *With Two Metals and One Liquid.*—When a piece of zinc and a piece of silver are immersed in mutual contact in a solution of nitrate of silver, the zinc dissolves and the silver receives a deposit, and an electric current is developed which circulates through the metals and liquids, and may be rendered further evident by connecting the metals with a galvanometer (Fig. 78): the zinc is positive, and the silver negative.

3rd. *With One Metal and Two Liquids.*—When two pieces of copper are immersed, one in dilute sulphuric acid, and the other in a solution of sulphate of copper, the two liquids being separated by a porous diaphragm, and the pieces of copper connected with a galvanometer, an electric current circulates, the piece of copper in the acid is positive and dissolves, and the piece in the metallic solution is negative and receives a deposit.

4th. *With Two Metals and Two Liquids.*—When a piece of zinc is immersed in dilute sulphuric acid, and a piece of silver in a solution of double cyanide of silver and potassium, and the two are connected with a galvanometer, the two liquids being separated by a porous partition, electricity circulates, the zinc is positive and dissolves, and the silver is negative and receives a deposit.

5th. *With a Separate Depositing Liquid.*—When two pieces of antimony, immersed in the ordinary chloride of antimony, are connected with any source of electricity, one piece becomes positive and dissolves, and the other negative and receives a deposit, and an electric current circulates, as may easily be proved by the galvanometer, in the foregoing manner.

6th. *With a Series of Depositing Liquids.*—If a series of depositing vessels (Figs. 73 and 75), containing solutions of sulphate of copper, and pieces of copper, are connected by their extreme pieces with a sheet of zinc, and a sheet of copper be immersed in a solution of sulphate of copper, every alternate piece of metal in the series will be electro-positive and dissolve, and every other alternate piece electro-negative and receive a deposit, and a current of electricity will circulate through the whole series.

37. *Electrical Conducting Circuit necessary.*—In every case where deposition is proceeding, the whole of the circuit must be capable of conducting voltaic electricity; and this is one important condition of the result; for if, in any such case, we interpose an imperfect electric conductor in the circuit such as a long iron wire, or a short

---

* See *ante*, p. 195.

† See *ante*, p. 178.

column of water, the process will be greatly impeded; and if we interpose a non-conductor of electricity, such as a rod of glass or of gutta-percha, or otherwise break the continuity of the circuit, deposition will be completely arrested.

38. *Electric Conductivity.*—The following is the general order of the conducting power of metals and alloys for voltaic electricity at 60° Fah., beginning with those which conduct most freely—viz., silver, copper, gold, cadmium, zinc, brass, tin, palladium, iron, steel, lead, platina, German silver, antimony, mercury, bismuth, potassium. The order is somewhat different at other temperatures.

39. *Direction of the Electric Currents.*—In every case where a current of electricity is developed by the mutual contact of liquids and metals, or where it merely passes through them, as in a separate depositing vessel, the current of *positive* electricity invariably passes from the positive or dissolving metal, *through the liquid*, to the negative or receiving one; and the negative electricity passes similarly in the opposite direction. When we speak of "*the current*," without stating which is meant—the positive or negative electricity—it is always intended, for the sake of simplicity of expression, to indicate the *positive* electricity: when we speak of the positive *metal* or *plate*, the metal which is positive and dissolves is meant; but when the positive *pole* is mentioned, the metal from which the positive electricity proceeds out of the arrangement or apparatus into the wires, and which is invariably the negative or receiving metal, is intended: for instance, when a piece of zinc and a piece of silver or copper are immersed in dilute sulphuric acid, the zinc is the *negative pole* and the *positive plate*, whilst the copper or silver is the *positive pole* and the *negative plate*.*

40. In a separate depositing vessel it is the dissolving metal which is called the positive plate, because it corresponds to the zinc or dissolving plate of the battery; while the receiving metal is called the negative plate: the term pole is also sometimes applied to those plates, but in an irregular manner.

41. *Electrical Decomposition of Liquids.*—In all cases of electro-deposition, the elements of the liquids are split asunder by electric action at the surfaces of the metals; the electro-negative elements, such as metalloids and acids, either combine with, or are set free at the surface of the dissolving or positive metal, and the electro-positive elements, such as metals and alkalies, either combine with, are set free, or deposited at the surface of the receiving or negative metal: for instance, if a piece of silver and a piece of copper are immersed in a solution of sulphate of copper, and a piece of zinc and a piece of platina are placed in dilute sulphuric acid, the silver connected with the zinc by one wire, and the copper with the platina by another wire, the *negative* elements of the liquid—namely, the sulphuric acid of the sulphate of copper solution, will be split from its associated copper, and will *combine* with the positive metal, the copper, causing it to dissolve in the liquid; while the *positive* element of the liquid—namely, the copper of the salt, will be deposited at the surface of the negative or receiving metal, the silver, but will *not combine* with it; but if we substitute a piece of platina for the piece of copper, and mercury for the silver (Fig. 74), the effects will be reversed, the acid or negative element will collect around the positive platina, but will *not combine* with it; whilst the positive element of the liquid, the copper, will be deposited and *combine* with the negative mercury. Fused salts yield the same substances by electric decomposition as the same salts do when dissolved in water.

42. *Electrical Terms in Deposition.*—For the more clear remembrance of the different parts of the circuit and of the direction of the electric forces, and for the better understanding of the action of the currents, Faraday has proposed the following terms, which have come into general use:—The liquid undergoing decomposition he terms an "*electrolyte*," from two Greek words, "electron," meaning "electric," and "luo," to "set free;" the act of electric decomposition he terms "*electrolysis*;" the metallic or other surfaces at which the electric forces enter and leave a liquid, he terms "*electrodes*," from two Greek words, "electron" and "odos," meaning a "way;" the positive electrode, or that point at which the positive electricity enters a liquid, is termed "*anode*," from two Greek words, "ana," meaning "upwards," and "odos," a "way"—the way in which the sun rises; and the negative electrode, or that by which the positive electricity leaves a liquid, is termed "*cathode*," from two Greek words, "cata," meaning "downwards," and "odos," a "way"—the way in which the sun sets; the elements of the liquid set free by electrolysis, he terms "*ions*," from a Greek word meaning "going;" those which combine with, or are set free at the anode, are termed "*anions*;" and those which combine with, or are set free at the cathode, are termed "*cations*."†

43. *Anions and Cations.*—Under the head of Anions may be classed—oxygen, fluorine, chlorine, bromine, iodine, and cyanogen; probably, also, sulpho-cyanogen, and the various mineral acids. Cations include—hydrogen (and ammonium), the alkaline metals, magnesium, manganese, arsenic, antimony, bismuth, zinc, cadmium, tin, lead, iron, cobalt, nickel, copper, mercury, silver, gold, platina, palladium, and the salifiable bases.

44. *Electro-chemical Scale.*—The various elementary substances have been arranged by Berzelius according to their relative degrees of positive and negative electro-chemical character, in a table or scale like the accompanying one, commencing with those substances possessing the strongest electro-positive properties, and ending with those of the strongest electro negative properties:—

POSITIVE END.

NAME.	SYMBOL.
Potassium	K.
Sodium	Na.
Lithium	L.
Barium	Ba.
Strontium	Sr.
Calcium	Ca.
Magnesium	Mg.
Glucinum	G.
Yttrium	Y.
Aluminum	Al.
Zirconium	Zr.
Thorinum	Th.
Cadmium	Cd.
Manganese	Mn.
Zinc	Zn.
Iron	Fe.
Nickel	Ni.
Cobalt	Co.
Cerium	Ce.
Lead	Pb.
Tin	Sn.
Bismuth	Bi.
Uranium	U.
Copper	Cu.
Silver	Ag.
Mercury	Hg.
Palladium	Pd.
Rhodium	R.
Platina	Pt.
Iridium	Ir.
Osmium	Os.
Gold	Au.

NAME.	SYMBOL.
Hydrogen	H.
Silicon	Si.
Titanium	Tit.
Tantalum	Ta.
Tellurium	Te.
Antimony	Sb.
Carbon	C.
Boron	B.
Tungsten	W.
Molybdenum	Mo.
Vanadium	Va.
Chromium	Cr.
Arsenic	As.
Phosphorus	P.
Selenium	Se.
Iodine	I.
Bromine	Br.
Chlorine	Cl.
Fluorine	Fl.
Nitrogen	N.
Sulphur	S.
Oxygen	O.

NEGATIVE END.

It will be observed, that the division indicated in the above table between gold and hydrogen, is, in a great measure, an arbitrary one; useful to assist the memory in recollecting the general electro-chemical character of the substances, but not really existing in nature: for instance, sulphur and chlorine, two of the most negative of substances, must be viewed as positive in relation to oxygen. A still more negative substance, when combined with that element, is hyposulphurous or hypochlorous acid, which is negative in relation to arsenic, hydrogen, zinc, potassium, when combined with those elements in the various metallic sulphides and chlorides: in fact, each substance throughout the scale may be viewed as both positive and negative—positive in relation to those below it, and negative in relation to those above it; those of the upper end being strongly positive and feebly negative, and those of the lower end strongly negative and weakly positive. It has been objected that sulphur and nitrogen occupy a position too near the negative end of the scale, they being generally less negative than chlorine and fluorine; also that hydrogen should be placed higher up in the positive division.

45. A consideration of all the foregoing facts leads us to conclude, that current electricity acts a most important part in all the phenomena of electro-deposition.

46. *Thermal Conditions.*—Under this head comparatively little can be said, because it is that portion of the subject which has been the least investigated; but it is highly probable that, as heat is generally evolved by the chemical combination of metals with metalloids or

---

* See *ante*, p. 194.

† See *ante*, p. 194.

with acids, there exist thermal as well as electrical and chemical conditions of deposition. In a series of experiments with two plates of antimony immersed in a conducting liquid, the two plates being maintained at different temperatures, and numerous liquids being tried, a weak current of electricity was developed, which passed from the hot metal through the liquid to the cold one, the hot metal thus being positive. This occurred in all cases except with liquids, containing uncombined nitric acid.

47. *Influence of Temperature on the Depositing Liquid.*—The strength of affinity between the different elements of a liquid undergoing electrolysis, varies with the temperature of the liquid; being almost invariably diminished by elevation of temperature. Rise of temperature increases the electric conductibility of an electrolyte, and decreases that of the metal plates immersed in it; but the decrease of conductibility of the latter is small in proportion, at moderate elevations of temperature, compared with the increase of the former; consequently, the general effect of heating a depositing liquid, is to increase the rapidity of deposition.

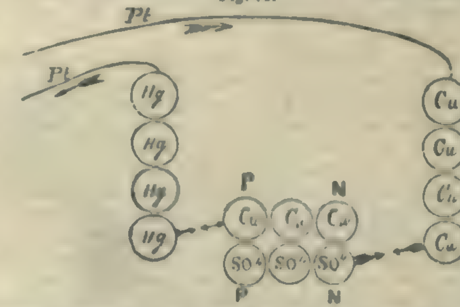
48. We have repeatedly observed, that with some solutions used at a high temperature for depositing, the cathode being immersed in the liquid at the ordinary atmospheric temperature, and the liquid then heated to the desired point, no conduction or deposition took place; nor did it occur when the receiving metal was taken out, washed in cold water, and re-immersed; but if the temperature of the liquid were first raised, and then the cold cathode suddenly immersed, deposition took place freely, and the liquid might be cooled down many degrees without stopping the action. In coating iron with tin in some solutions, the iron being immersed before heating the liquid, no deposition took place even at 150° Fah.; but if the liquid were first heated, deposition occurred below 100° Fah.

49. *Influence of Light upon Deposition.*—Light appears to exercise much less influence upon electro-deposition than heat: in some cases, however, where the elements of a depositing liquid are held together by unstable affinities, it decomposes the liquid, and renders it unfit for deposition. For instance, a solution formed by dissolving hyposulphate of silver in a solution of hyposulphite of soda, has a tendency to be decomposed in this way.

50. *Dynamic or Mechanical Conditions.*—The various phenomena occurring in a liquid undergoing electrolysis, may be viewed, in a mechanical or dynamic aspect, as a series of minute movements (attractions and repulsions) occurring between the various particles of matter composing the opposed surfaces of the liquids and of the metals immersed in them. For instance, if we immerse a piece of zinc in a solution of sulphate of copper, and connect it with some mercury in the same liquid, by a platina wire protected from the solution by a tube of glass or gutta-percha, the particles composing the surface of the zinc, being all electro-positive, will tend to repel each other, and the particles of the liquid surface in contact with it, being rendered electro-negative, will also tend to repel each other; whilst the particles of acid near, being electro-negative, will attract the particles of zinc, which are electro-positive, and the two will combine together and form a salt; at the same time, the particles of the liquid surface in contact with the mercury, being made electro-positive, will tend to repel each other. The particles of the opposed mercury surface, being rendered electro-negative, will also tend to repel each other; whilst the particles of the mercury, being electro-negative, and the contiguous particles of copper in the liquid being electro-positive, the two will combine together and form an alloy. The deposition of copper upon the *zinc*, in this case, must be wholly disregarded, because it is quite a separate and distinct phenomenon.

To put this in a clearer form—suppose (Fig. 79) the vertical row of particles Cu, Cu, Cu, Cu, to represent the copper anode of a sulphate of copper depositing liquid, and the row of particles Hg, Hg, Hg, Hg, to be the mercury cathode, Pt, Pt being the connecting wires from the battery, and the double row representing the particles of acid SO^4. and copper Cu, composing the intervening liquid. The particles of the anode surface, being all electro-positive, tend to repel each other; and the contiguous particles of Cu and SO^4, being all negative, also tend to repel each other; whilst the particles of the copper anode, being positive, attract the nearest particles of negative acid, and combine with them, and form a salt. At the same time, the particles of Cu and SO^4 nearest the mercury, being all positive, tend to repel each other; whilst the contiguous particles of mercury being negative, and the copper in the liquid being positive, attract and combine with each other and form an alloy. By this combination of simultaneous movements, the copper anode dissolves, the mercury (or any other conducting substance which forms the cathode) receives a deposit, and the particles of copper of the liquid are gradually removed and replaced by those from the anode.

Fig. 79.



51. These attractions and repulsions, like ordinary chemical actions, are all supposed to take place at insensible distances, at the mutually opposed surfaces of the liquids and metals, and not to extend into their masses, except so far as they are mixed with each other by capillary attraction or ordinary mechanical motion, and can therefore only take place where one or both of the substances are in a liquid state; if it were otherwise, the combinations and decompositions of the whole masses would probably occur instantaneously.

52. In addition to these minute and invisible movements of the particles, there are other and sometimes visible movements produced by capillary attraction and by difference of specific gravity in the liquids. For instance, the salt formed at the anode, if it be soluble in the liquid, will be dissolved and gradually diffused through it by capillary attraction or adhesion; whilst from its greater specific gravity than the remainder of the liquid when dissolved, it tends to sink towards the bottom; at the same time, the acid set free at the cathode is likewise gradually diffused through the liquid by similar means, and from its less specific gravity tends to rise to the surface. These movements are of general occurrence during deposition; and in some solutions, especially if they are very dense and possess a colour, they are plainly visible to the unassisted eye. Their occurrence explains why the substances set free by deposition are not instantaneously transferred from one electrode to the other, but occupy, especially in dense liquids and electrodes far asunder, a considerable period of time in their transference; it also explains why, if depositing solutions are not occasionally stirred, their upper portions become exhausted of metal, whilst their lower parts become deficient of acid. Motion of the cathode is generally considered necessary to make the deposited metal harder.

53. *Position of the Electrodes.*—The position of the electrodes has a considerable influence upon the phenomena of electro-deposition. For instance—1st. If the two electrodes in a depositing liquid are horizontal, with the anode above and the cathode below, the salt formed at the anode will, by virtue of its greater specific gravity, sink in the liquid; whilst the acid set free at the cathode will, by its less specific gravity, rise upwards, and thus the anode will be constantly supplied with fresh uncom-

bined acid, the cathode will receive a constant supply of metallic salt, and deposition will continue without interruption. 2nd. If the two electrodes are vertical in the liquid, and opposite to each other, similar differences of specific gravity will cause the lower part of the liquid to become saturated with metallic salt, and its upper part to consist of free acid mixed with the water: in consequence of this, the current of electricity will almost wholly pass from the upper part of the anode diagonally downwards through the liquid, to the lower part of the cathode, and thus the upper part of the anode will dissolve rapidly, whilst its lower part will dissolve but slowly, and the cathode will receive a rapid deposit at its lower part, and but very little at its upper part. In this position, vertical lines, and even deep grooves, are sometimes produced in the deposit (especially if the position of the cathode be slightly overhanging), by the ascent of streams of the lighter acid liquid from which the metal has been exhausted by deposition. If the solution be nearly a saturated one, and has been freely worked without stirring or disturbance for some time, crystals of the metallic salt are apt to form all over the lower part of the anode, which will be dissolved very rapidly at the surface of the liquid, and appear as if cut by a knife. In addition to these effects, if the solution be a very deep one, with much free acid, two independent currents of electricity will be developed, one in each electrode, by the unequal action of the two different strata of liquid upon their upper and lower parts. An instance of this will be found in "One Metal and Two Liquids" (9), in which these currents leave them at their upper parts, pass down through the liquid, and re-enter them at their lower extremities.

54. *Form of the Electrodes.*—If either of the electrodes be of an irregular form, or have unequal projections or hollows, the anode will dissolve most freely, and the cathode receive the greatest deposit of metal at those parts at which they are nearest each other, and least in the hollows and more distant parts. If the surface of the cathode be rough, it greatly increases the tendency of the deposit to become crystalline.

55. *Mathematical Conditions.—Definite Chemical Action.*—In the combination of different elementary and compound substances with each other, by ordinary chemical affinity, it has been observed, and accurately proved by analysis, that their combinations invariably take place in certain definite proportions, or in very simple multiples of those proportions; and as in the first of these cases it is inferred that their combinations with each other occur, atom with atom, the numbers which represent those simple proportions represent also the relative weights of those atoms to each other. The following table contains the names, symbols, and atomic weights of most of the simple or elementary substances:—

Name.	Symbol.	Atomic weight.
Hydrogen	H	1·0
Beryllium	Be	4·7
Carbon	C	6·0
Lithium	Li	6·5
Oxygen	O	8·0
Boron	B	10·9
Magnesium	Mg	12·2
Aluminum	Al	13·7
Nitrogen	N	14·0
Sulphur	S	16·0
Fluorine	Fl	18·9
Calcium	Ca	20·0
Silicium	Si	21·3
Zirconium	Zr	22·4
Sodium	Na	23·0
Titanium	Ti	25·0
Chromium	Cr	26·7
Manganese	Mn	27·6
Iron	Fe	28·0
Cobalt	Co	29·5
Nickel	Ni	29·6
Copper	Cu	31·7
Phosphorus	P	32·0
Zinc	Zn	32·6
Chlorine	Cl	35·5
Potassium	K	39·2
Selenium	Se	39·5
Strontium	Sr	40·8
Molybdenum	Mo	46·0
Lanthanum	La	47·0
Cerium	Ce	47·0
Didymium	D	50·0
Rhodium	R	52·2
Ruthenium	Ru	52·2
Palladium	Pd	53·3
Cadmium	Cd	56·0
Tin	Sn	59·0
Thorinum	Th	59·6
Uranium	U	60·0
Tellurium	Te	64·2
Barium	Ba	68·5
Vanadium	Va	68·6
Arsenic	As	75·0
Bromine	Br	80·0
Tungsten	W	95·0
Platina	Pt	98·7
Iridium	Ir	99·0
Osmium	Os	99·6
Mercury	Hg	100·0
Lead	Pb	103·7
Silver	Ag	108·1
Iodine	I	127·1
Antimony	Sb	129·0
Tantalum	Ta	184·0
Gold	Au	197·0
Bismuth	Bi	213·0

56. As there is a number of compound substances used in electro-deposition, such as sulphuric acid, cyanide of potassium, &c., and it will be useful to the practical depositor to know their combining proportions in making the different salts, used in the art, we have selected those which are likely to be required, and give their names, symbols, and atomic weights or combining proportions:—

Water, HO; 9·0.

Common Oil of Vitriol, specific gravity, 1·848; SO^3, HO; 49·0.

Strongest Hydrochloric Acid, sp. gr. 1·21; HCl, 6HO; 90·5 (*i.e.*, 90 and 5-tenths).

Strongest Nitric Acid, sp. gr. 1·52; NO^5, 2HO; 72·0.

Sesquicarbonate of Ammonia (Sal-volatile); 2 NH^3, $3CO^2$, 2HO; 118·0.

Hydrochlorate of Ammonia (Sal-ammoniac); NH^3, HCl; 53·5.

Hydrate of Potash (fused Caustic Potash); KO, HO; 56·2.

Crystallised Carbonate of Potash; KO, CO^2, HO; 78·2.

Carbonate of Soda (ordinary washing Soda); NaO, CO^2, 10HO; 143·0.

Chloride of Sodium; Na Cl; 58·5.

Caustic Lime; CaO; 28·0.

Calcined Magnesia; MgO; 20·2.

Ordinary Carbonate of Magnesia; MgO, CO^2, HO; 51·2.

Oxide of Zinc; *Zn*O; 40·6.

Commercial Sulphate of Zinc (White Vitriol); ZnO, SO^3, 7HO; 143·6.

Sesquioxide of Iron (Crocus, Colcothar); Fe^2O^3, 80·0.

Commercial Sulphate of Iron (Green Vitriol); FeO, SO^3, 7HO; 139·0.

Protoxide of Copper (Black Oxide of Copper); CuO; 39·7.

Oxide of Silver; AgO; 116·1.

Commercial Sulphate of Copper (Blue Vitriol); CuO, SO^3, 5HO; 124·7.

Chloride of Silver; Ag Cl; 143·6.

Nitrate of Silver; AgO NO^5; 170·1.

Oxide of Gold; AuO; 205·0.

Terchloride of Gold; Au Cl^3; 303·5.

Bichloride of Platinum; Pt Cl^2; 169·7.

Cyanogen; Cy; 26·0.

Cyanide of Potassium; KCy; 65·2.

Cyanide of Zinc; Zn Cy; 58·6.

Sesquicyanide of Copper; Cu^3, Cy^2; 147·1.

Cyanide of Mercury; Hg Cy; 126·0.

Cyanide of Silver; Ag Cy; 134·1.

Cyanide of Gold; Au Cy; 223·0.

57. *Definite Electro-Chemical Action.*—The chief mathematical condition of electro-deposition is, that in every case, all the actions, both of combination and decomposition, take place in certain mathematical proportions; that is, according to the relative atomic weights of the substances combining or being decomposed. For instance—

1st. *With One Metal and One Liquid.*—If a piece of pure iron be immersed in a solution of sulphate of copper, it will be dissolved, and copper deposited; and for every 28 parts, or one atomic combining equivalents of iron dissolved, 31·7 parts, or one atom, of copper are deposited, and 49 parts (one equivalent) of hydrated sulphuric acid (common oil of vitriol) are separated from the copper, and combine with the iron, forming therewith one equivalent of protosulphate of iron.

2nd. *With Two Metals and One Liquid.*—If a piece of zinc and a piece of silver in mutual contact are immersed in a solution of nitrate of silver, the zinc will dissolve and the silver receive a deposit; and for every 108·1 parts of silver deposited, 32·6 parts of zinc will be dissolved.

3rd. *With One Metal and Two Liquids.*—If one piece of copper be immersed in a solution of sulphate of copper, and another in dilute sulphuric acid, the two being connected together by a wire, and the liquids separated by a porous partition, copper will be dissolved in the dilute acid in the proportion of 31·7 parts for every 31·7 parts of copper deposited in the metallic solutions; and for every 49 parts, or one equivalent, of hydrated sulphuric acid set free at the cathode by the deposition of the equivalent of copper, one equivalent of acid will combine with a like amount of copper at the anode.

4th. *With Two Metals and Two Liquids.*—If we immerse a piece of zinc in dilute sulphuric acid, and a piece of silver in a solution of double cyanide of silver and potassium, the two metals being connected by a wire, and the liquids separated by a porous partition, one equivalent, or 32·6 parts, of zinc will combine with one equivalent of the acid, and one equivalent, or 108·1 parts, of silver will be deposited, setting one equivalent, or 26 parts, of cyanogen free.

5th. *With a Separate Depositing Liquid.*—If the plates of a battery are connected by wires with two pieces of gold in a hot solution of double cyanide of gold and potassium, for every atomic equivalent, or 197 parts of gold deposited, and one equivalent of cyanogen set free, one equivalent of gold will combine with one equivalent of cyanogen, and will be dissolved: and not only this; but for each of these actions, one equivalent of zinc will combine with one equivalent of acid, and one equivalent of hydrogen will be evolved in each of the battery cells supplying the current of electricity.

6th. *With a whole Series of Depositing Liquids.*—Such, for instance, as solutions of sulphate of copper with electrodes of copper—arranged as in Figs. 73 and 75—connected with a piece of zinc immersed in dilute sulphuric acid, and a piece of copper immersed in a solution of sulphate of copper, the last two liquids separated by a porous diaphragm, the whole of the combinations, decompositions, and depositions throughout the series, will take place in the proportions of their atomic weights or chemical equivalents. These, and many other instances which might be adduced, prove that all the electro-chemical actions taking place in any given circuit, occur in certain definite proportions, and that this definite electro-chemical action is one very important condition of electro-deposition.

58. *Binary Theory of Electrolysis.*—The law of definite electro-chemical action was first established by Faraday; and, in addition, he has advanced what is termed the binary theory of electrolysis—that "only those compounds of the first order are *directly* decomposible by the electric current, which contain one atom of one of their elements for each atom of the other: for instance, compounds containing one atom of hydrogen or metal with one atom of oxygen, iodine, bromine, chlorine, fluorine, or cyanogen;" whilst "boracic acid ($B\,O^3$), sulphurous acid ($S\,O^2$), sulphuric acid ($S\,O^3$), iodide of sulphur, chloride of phosphorus ($P\,Cl^3$) and ($P\,Cl^5$), chloride of sulphur ($S^2\,Cl$), chloride of carbon ($C^4\,Cl^6$), bichloride of tin ($Sn\,Cl^2$), terchloride of arsenic ($As\,Cl^3$), quintochloride of antimony ($Sb\,Cl^5$)," are non-conductors of electricity, and incapable of electrolysis. Some substances, which are not of the simple binary character mentioned, are decomposed by current electricity, and yield their positive and negative elements in equivalent proportions at the respective electrodes; but, according to this theory, they are *indirectly* decomposed, *i.e.*, they are decomposed by the chemical action of some of the elements set free by the direct action of the current upon other substances present. For instance, "fused borax (biborate of soda $NaO, 2BO^3$) yields oxygen gas at the anode, and boron at the cathode: now, since fused borax is not decomposible by the electric current, the separation of the boron must be attributed to indirect action; the current resolves the soda (NaO) into oxygen and sodium, and the latter separates boron from the boracic acid."* Again, an aqueous solution of ammonia (HO, NH^3) yields, by electrolysis, nitrogen gas at the anode, and hydrogen at the cathode. In this case, according to the theory, it may be supposed that only the water (HO) is *directly* decomposed, and that its oxygen, set free at the anode, combines chemically with some of the hydrogen of the ammonia, again forming water, and thus indirectly the nitrogen is set free.

59. *Mathematical Idea of Electro-depositing Force.*—A consideration of the law of definite electro-chemical action, and the binary theory of electrolysis, leads us to view the electric current or depositing force in a mathematical aspect, as "an axis of forces equal in power, but opposite in direction;" because, for every atom of an electro-positive substance attracted or transferred in one direction, an atom of an electro-negative character is attracted in the opposite direction. It also suggests to us the idea that an intimate connection exists between those equivalents or mathematical relations of matter and the development of current electricity by chemical action, and its transference through liquids by electrolysis, because these phenomena only occur when the mathematical conditions are present.

60. *Sizes of Electrodes, Liquids, and Wires.*—The rapidity of deposition is influenced by the area of the electrodes, the length and area of the intervening liquid, and of the connecting wire; the larger the immersed surfaces of the metals, the shorter the length and the greater the transverse area of the liquid between them; and the shorter and thicker their connecting wires, the more rapid is the process of deposition. If the anode be very large, and immersed in the lower part of the liquid, and the cathode very small and suspended near the surface, much more metal will be dissolved than is deposited, gas being generally evolved at the cathode in place of some of the metal being deposited.

61. *Rapidity of Deposition.*—The character of the deposited metal is very much influenced by the rapidity of deposition: if it be deposited very rapidly, it will be in the state of a perfectly black, soft, non-coherent powder; if deposited more slowly, it will possess the ordinary characters of the particular metal; and if deposited very slowly, it will be crystalline, because the atoms are then allowed sufficient time to arrange themselves in the crystalline form.

62. *Logical Conditions.*—The logical conditions are—1st, that there is a *difference* at the dissolving and receiving surfaces, either in the "*material substratum*" of metal, of liquid, in the *forces* involved, or in all combined, both of chemical affinity and electricity—probably, also, of heat and of motion; and, 2nd, that in all cases of deposition there are certain chemical, electrical, thermal, dynamical, and mathematical conditions invariably present, and certain other conditions of each of those kinds invariably absent, both of which classes of conditions are necessary to the production of the phenomena; the whole of the necessarily present circumstances constituting its causes, and all the necessarily absent ones constituting its preventives. Thus, if *all* the causes of deposition are present, and *all* its preventives absent, deposition will invariably occur; but if only one of its causes is absent, or one of its preventives present, deposition cannot take place.

63. *Ontological Condition.*—The last, the most necessary, most evident, and most simple condition of all deposition is—that metals, liquids, and forces are required in order to produce it.

THE PRACTICE OF ELECTRO-DEPOSITION.

64. *Objects of Practical Deposition.*—In the theoretical division we have brought forward a large number of instances, both of deposition and non-deposition; and from a consideration of them, we have drawn conclusions both as to what substances, and what conditions and arrangements of those substances, really exist in all cases of deposition, and in similar cases of non-deposition; and we have pointed out in what respect the conditions varied. Our object in pursuing this course was to impress the reader with an extended knowledge of the theoretical principles on which deposition proceeds, that he may feel himself perfectly able to apply his knowledge to remove the difficulties certain to arise in his practice. Now, however, our object is different; it is to instruct the reader how he is to apply those principles in daily working; to give him practical rules, recipes, and directions for carrying out the various minute points in workshop manipulation; and to enable him to obtain the greatest degree of practical success.

---

* Faraday.

65. *General Arrangement of Electro-Deposition.*—The practical part will be best arranged by beginning at the very commencement; and assuming the reader to be without materials or apparatus of any kind—that he has to provide a workshop, prepare his solutions, batteries, scouring and cleaning apparatus; that he has to clean his articles for receiving deposits, and prepare his materials for moulds, before he can commence the process of deposition, gradually acquiring a knowledge, as he proceeds, of the kind of depositing process best fitted for his purpose; of the most suitable source of depositing power; the best solutions; the best recipes for making solutions; the construction of voltaic batteries and of magneto-electric machines; the rules for regulating the currents of electricity, and the character of the deposited metals; rules for depositing metals generally, as well as for cleaning and preparing metal articles to receive deposits; copying works of art by moulding; preparation of moulds for receiving deposits; making solutions for ordinary coppering, silvering, and gilding; and for the management of those solutions;—information on all these points it will be our task to supply.

66. *First Considerations.*—The first step in practice is, to consider the probable magnitude of the operations to be carried on, and to provide rooms of suitable size. These should be upon the ground-floor (except for electro-gilding), well lighted and ventilated, with conveniences for the erection of boilers and drying flues, for placing washing-troughs, depositing vats and batteries, and for the escape of unwholesome vapours; there should also be ready access to a plentiful supply of clean water. The establishment should consist of at least three rooms, and an open yard with an outhouse; an upper or more private room for gilding, a ground-floor room for silvering, and another ground-floor room for the coarser work, such as coppering, brassing, and the preparation of the larger and coarser articles for receiving deposits. The outhouse is for the batteries, and the yard for washing the battery cells. If a magneto-electric machine be employed, an additional small, dry, and clean apartment will be required, which should be reserved for it alone.

67. *Boilers, Furnaces.*—For the purpose of general deposition, several large iron boilers, with furnaces beneath, either in the coppering-room or in close proximity to the silvering-room, are required; these are to contain solutions of caustic potash for cleaning articles. A low furnace should be erected between those rooms, having a long horizontal flue covered with plates of iron for drying deposited or plated articles upon; the room for coppering should be furnished either with a low furnace or stove for heating the solutions used for coppering or brassing iron. Each room, whether for coppering, silvering, or gilding, should be provided with a tap of running water, and a leaden trough beneath, for washing the smaller articles; and the coppering-room should be furnished with one or two large wooden tubs or troughs, filled with water, for washing articles of larger size. This room and the outhouse should contain a number of large stoneware pans and jars, oval and round, of different sizes and proportions, to receive the various "pickling" and "dipping" liquids, acids, or "spent solutions." Several large iron trays, filled with sawdust, should also be provided and fitted to the furnace flue, for drying plated and deposited articles upon. Each of the rooms should be provided with a "scratch-brush lathe," for scouring the various articles. The gilding-room should have several small stoves for heating gilding solutions, or, in lieu thereof, several iron tripods, with large gas-burners beneath. The silvering and coppering-rooms should each be provided with one or two pairs of large and well-insulated copper wires, proceeding from the depositing vats to the batteries outside. The gilding-room will not require these, small batteries only being used in it, which are kept in the same room.

68. *Sources of Electricity.*—A point for early consideration will be, whether a magneto-electric machine or voltaic batteries are to be used as the source of depositing power. The choice of either will depend very much upon the degree of confidence the operator possesses in each source of electricity, upon its expense, and whether or not motive power to drive the former, is readily and constantly available at a moderate cost. Voltaic batteries are readily obtained, and worked in almost any situation. We will suppose, for the purpose of explanation, that the operator has resolved to use both a magneto-electric machine and voltaic batteries.

69. *Construction of Magneto-Electric Machine.*—The simplest form of apparatus for generating current electricity by the joint influence of magnetism and motion, has been already described (15); but the apparatus required for practical purposes is far more elaborate and costly in its construction. A (Fig 80) is a strong framework of wood; B, B, B, B, are four bundles of powerful horse-shoe magnets, firmly fixed to the wooden frame; C is an axle driven very rapidly by steam-power; the axle carries two brass circles, upon which, at right angles, are firmly fixed four round bars of pure soft iron, B, C, D, E (Fig. 82), equal in length to the distance asunder of the poles of each magnet; upon each of these is coiled a long piece of thick copper wire, the wire being covered with cotton to insulate its coils from each other; the ends of these wires are connected with four semicircular pieces, formed of a piece of brass tube, fixed upon the axle C, but insulated from it and from each other (Fig. 81) by a tube of hard wood or gutta-percha: by rotation of the iron armatures past the poles of the magnets, currents of electricity are generated in the wires in one direction as they are approaching the magnets, and in an opposite direction as they recede from them: to collect those currents and convey them to the depositing vat, also to throw them all into one uniform direction, two brass springs, D E (Fig. 81), press against the semicircles of brass during their revolution, and are so arranged at their points of mutual contact, that, just at the moment that the currents are changed in direction by the armatures passing the magnets, the revolution of the axle causes the points of contact of the springs to pass from one pair of the semicircles to the other; and thus, by reversing the connection at the moment the direction of the current is changed, a uniform direction of currents is obtained in the wires beyond.

Fig. 80

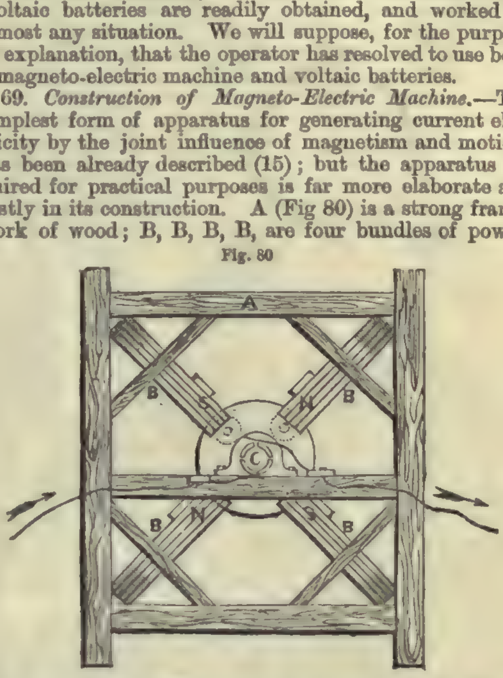


Fig. 81.

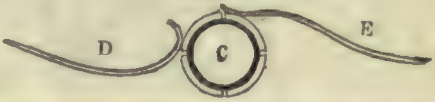
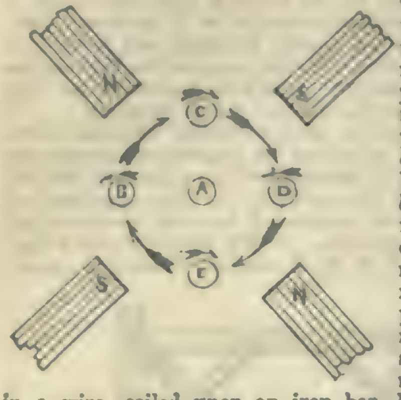


To explain the action of this machine more fully, we will suppose NS, NS (Fig. 82) to represent those poles of the compound horse-shoe magnets which are placed facing the observer in the elevation (Fig. 80); A in Fig. 82, is the axle, and B, C, D, and E are the ends of the four horizontal round iron bars or armatures, moving in the direction of the large arrows. When a bar of soft iron, having a coil of insulated wire wound upon it, is moving *towards* a pole of a magnet, a current of electricity is developed in the wire in *one* direction by the piece of iron within it *gaining* magnetism; and when the bar is moving *from* the pole of the magnet, a current is produced in an *opposite* direction by the iron bar *losing* its magnetism; and these currents are both reversed in direction, if the pole of the magnet be reversed; so that the current developed in a wire, coiled upon an iron bar, by moving that bar *towards* the *south* pole of a magnet, is the same in direction as that produced by moving it *from* the *north* pole. We will now suppose that the current produced in the coil of wire upon bar B, moving from S to N, is in the direction of the small arrow surrounding that bar—viz., *left*-handed motion; if so, the current of the wire of bar D will also be *left*-handed in direction, because it also is moving from a south to a north pole; whilst the currents in the wires of bars C and E will be *right*-handed, because both those bars and coils are moving from north to south poles.

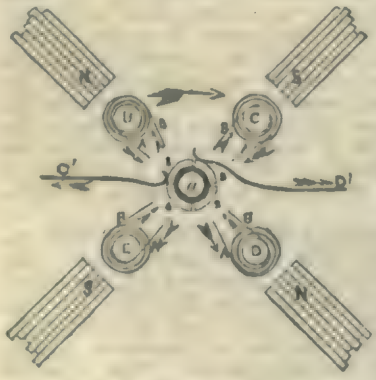
Fig. 82.



From these remarks, it may be perceived—1st, that the currents of electricity, in all the coils, are reversed in direction every time the bars pass the centres of the poles of the magnets, *i.e.*, four times in every revolution; 2nd, that to obtain a current of one uniform direction from all the four coils (by conducting the whole four into one stream), during *only one quarter* of a revolution, *i.e.*, from one pole to the next one, it is necessary to connect the ends of the wires of the coils of B and D in an opposite manner with the semi-cylinders of the commutator or break-piece (Fig. 81), to those of the coils of C and E; and, 3rd, that as the currents in all the coils are reversed in direction every time the bars pass the centre of the poles of the magnets, the two springs which press upon the semi-cylinders, must, by some means or other, be reversed in their order of connection with all the wires every time, and at the same moment that the bars pass the centres of the poles, in order to throw the whole of the currents, during a complete revolution, into one uniform direction in the springs and in the wires which proceed to the depositing vessel.

To enable us to understand how the opposite currents of the different coils are thrown into one uniform direction during one quarter of a revolution, and how the whole of the currents are alternately conducted into one uniform stream during rapid revolution, we will suppose *a* (Fig. 83) to be the axle, and 1, 2, 3, and 4, the semi-cylinders insulated from the axle by a tube of gutta-percha. In the first place 1 and 2 are connected together by a short piece of thick copper or brass wire, or a strip of sheet copper behind (not shown in the cut), and 3 and 4 are connected together by another and similar piece of metal; next the ends of the wires A, A, A, A are gathered into one bundle, and connected by soldering with the wire or strip of metal of the semi-cylinders 1 and 2, and the ends B, B, B, B are connected in like manner with the semi-cylinders 3 and 4; and by this arrangement, on careful attention, it will be perceived that the whole of the currents are thrown into one direction during *one quarter* of a revolution. In the sketch, the bars are just approaching the centres of the poles, and the semi-cylinder 1 is just about breaking contact with spring C′, and semi-cylinder 4 is about making contact with it; semi-cylinder 3 is about passing from spring D′, and semicircle 1 is about making contact with it. In this position of the bars, it will be perceived that all the A ends of the wires, the semi-cylinders 1 and 2, and the spring C′, are positive, as indicated by the arrows; whilst the B ends, the semi-cylinders 3 and 4, and the spring D′ are negative: but immediately the bars pass the centres of the poles, the currents are all reversed in direction—all the B ends of the wires, and the semi-cylinders 3 and 4 become positive, and the A ends, and the semi-cylinders 1 and 2 negative; but as the rotation of the axle shifts the points of contact of semi-cylinder 1 to spring D′, and of semi-cylinder 4 to spring C′, at the same moment, the spring C′ still remains positive, and D′ negative, as before. The connections of the springs with the semi-cylinders in the other two quarters of the revolution, alternate in a similar manner; and these alternations take place regularly, and synchronously with the reversals of the currents, during the most rapid revolutions; and notwithstanding the incessant and indefinitely rapid changes of these currents, one uniform stream of electricity is obtained. In the practical machine, the bars of iron rotate as closely as possible to the ends of the magnets without absolutely touching them, in order to obtain the greatest amount of power; and the power is regulated by placing the soft iron keepers which are upon the magnets (Fig. 80) nearer or further from the poles; the keepers are secured to the magnet, that they may not fall off by the vibration of the machine. The wires proceeding from the springs are connected, one with the dissolving plates, and the other with the receiving articles in the vat. The machine may contain eight revolving armatures, and either four or eight magnets, according to the amount of work to be effected.

Fig. 83.



70. *Voltaic Batteries.*—Each of the arrangements of metals and liquids which have been described under the head of "Facts," and which develop a current of electricity, constitutes an elementary voltaic battery—a battery in all its essential parts, but not in outward form. All voltaic batteries consist of one or other of those theoretical arrangements modified and adapted for practical use, and are composed either of two metals and one liquid, or two metals and two liquids; because these two arrangements develop the greatest amount of electricity, and are most convenient in use. In the theoretical form, any kind of metal, of any size or shape, with almost any conducting liquid, and with any kind, shape, or size of containing vessel, will develop a current of electricity and produce deposition; but a true voltaic battery consists of particular metals and liquids, of particular sizes, shapes, and proportions, and at certain distances apart, with suitable screws attached for connections, and with containing-vessels made of particular materials, and of special forms and sizes.

71. Arrangements of various voltaic batteries have already been fully described in our previous pages.*

72. *Battery Cells.*—The form of cells for these batteries is generally either round or square; for *small* batteries, either of the old zinc and copper kind, or of Mr. Smee's arrangement, square ones are generally used; but for small Daniell's batteries, or for large batteries of either of these kinds, round vessels are almost invariably adopted. They are made of stoneware, glass, or gutta-percha; the first of these is universally used for large batteries of all kinds: glass is too expensive for large vessels, but it possesses the great advantage of enabling the operator to watch the action of the

* See *ante*, p. 187, *et seq.*

batteries, and is now being moulded into large vessels for the use of some of the electro-plate manufacturers: gutta-percha has been also used, but possesses rather less advantage, upon the whole, than the other materials, being opaque and expensive, while the zinc salt of the battery liquid passes rather rapidly over its edges by capillary action.

73. *Porous Cells.*—When Daniell's or any other battery with two liquids is used, porous vessels are required also, to allow the two liquids to touch each other without mixing: they are of three kinds—unglazed earthenware, wood, and bladder. The first of these is the only kind in use by manufacturers; they should always be kept in clean water when not in use, to remove the salts of the battery liquids from them, to prevent their cracking, and to preserve them always fit for immediate use.

74. *Zinc for Batteries.*—The best kind of zinc for batteries, and the kind chiefly in use by electro-platers, is the German or Liége zinc, known as "Mosselman's," from the name of a former manufacturer of it. The thickness of the plate should vary with the size of the battery; the smallest should not be less than one-eighth of an inch thick, on account of its brittleness when amalgamated; large ones are generally about one quarter or three-eighths of an inch in thickness. Zinc bolts for Daniell's batteries are generally made by melting together a number of old worn-out pieces of battery plates, and casting in a suitable mould.

75. *Amalgamation of Zinc.*—Zinc plates or bolts are best amalgamated by immersing them, during a quarter of an hour, in a mixture of about one part of sulphuric acid and ten or twenty parts of water; then pouring mercury upon them, and rubbing it all over them with a hare's foot or piece of old cloth, using a small hard brush for the refractory places; they are then washed in water, and drained for half-an-hour, and brushed, to recover the superfluous mercury.

76. *Copper and Platinised Silver for Batteries.*—Ordinary sheet copper answers very well for this purpose, and platinised silver may be obtained of most philosophical instrument-makers, or it may be easily prepared by any one by the following means:—Immerse a piece of zinc in dilute sulphuric acid contained in a porous cell; place the cell in an outer vessel, and fill the outer space with water, to which a few drops of sulphuric acid have been added; add to this a sufficient quantity of a solution of bichloride of platina to render it of a brown colour; immerse the piece of silver to be platinised in the outer liquid, and connect it by a wire with the piece of zinc; gas will soon be evolved from the surface of the silver, when the silver will gradually become black with a deposit of platina; it may then be removed, dipped several times in water, and afterwards dried, care being taken not to rub off the platina. The porous cell requires to be immersed a short time beforehand. The solution of bichloride of platina may be easily and cheaply made by adding scraps of the metal foil to a hot mixture of one measure of nitric acid and two-and-a-half measures of hydrochloric acid, as long as gas is evolved from them; the liquid will then be of a deep red colour.

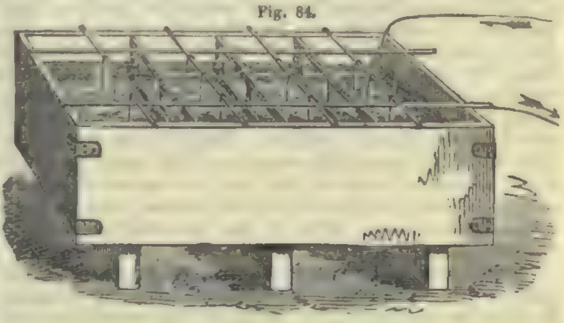
Silver alone is not nearly so effective for the negative metal of voltaic batteries as platinised silver, because the hydrogen gas evolved adheres very strongly to it, and greatly reduces the amount of its surface in contact with the liquid; whereas the platina being a very negative metal, and being deposited in the state of a fine powder, causes the hydrogen to be thrown off very rapidly from its surface, and thus increases the action.

Copper is still less effective than silver, because the battery liquid acts chemically upon it, and forms a salt of copper, which dissolves in the liquid and reacts upon the zinc plates, causing them to waste rapidly; for this reason they cannot, like silver, be safely left in the liquid any great length of time when the battery is not at work. In addition to this, when they are taken out and exposed to the air, they soon become covered with a film of oxide, which considerably weakens the electric current on their reimmersion.

77. *Depositing Vessels, Vats, &c.*—The depositing vessels are made of various materials. For small operations, nothing is so suitable as glass vessels or a stoneware pan; but for ordinary manufacturing purposes, vats containing from twenty to several thousand gallons are used: they are generally made of wood, lined with sheet lead; but very large ones, for containing sulphate of copper solution, such as are used for depositing life-sized figures in copper, have in some instances been built of bricks, coated with cement, and lined with gutta-percha. Vats used to contain cyanide solutions should not be lined with this substance, because the cyanide of potassium acts upon it. The vats used for ordinary silver-plating are about twenty-four or thirty inches deep, from two to three feet wide, and from three to twenty feet long; their dimensions vary greatly in different manufactories, and depend upon the number and size of the articles to be plated in them. Some electro-depositors use vats formed of sheets of wrought-iron riveted together; but there is always a slight salt or sediment found on their sides, which settles at the bottom of the liquid.

78. *Arrangement of Dissolving Plates in Vat.*—In the vats used for silvering general articles, such as spoons, knives, forks, teapots, plates, &c., the dissolving plates are sometimes fixed all round the sides of the vessel just beneath the surface of the liquid; in addition to this, vertical wooden frames are fixed at intervals of about two feet, across the vat (Fig. 84), with dissolving plates upon them, and all the dissolving plates are connected together metallically. The articles to be plated are suspended by small copper wires, from brass or copper tubes resting across the vessel upon two other and longer tubes passing along the upper edges of the vat. These are connected by a large copper wire with the negative pole of the battery; whilst the dissolving plates are connected by another large copper wire with the positive pole: by this arrangement, each row of articles has dissolving plates all round it, which greatly facilitate the rapidity of deposition. The wooden cross-frames are movable, so that when large articles are to be plated, one or more of them may be removed to make more room.

Fig. 84.

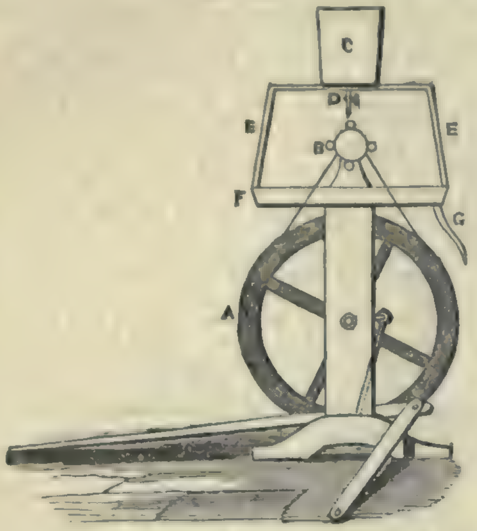


79. The large vessels used for depositing solutions which require to be worked *hot*, such as the cyanide coppering or brassing liquids, are formed either of cast-iron, wrought-iron, or iron coated with enamel; and the smaller vessels, such as are used for gilding, are oftentimes of stoneware or glass; enamelled iron pans are also used for this purpose.

80. "*Scratch-brush Lathe.*"—The deposition will require several "scratch-brush" lathes, one in each depositing-room, for scouring and preparing the surfaces of metal articles to receive a deposit. This instrument (Fig. 85) consists simply of an ordinary lathe A, with a wooden chuck B, to the sides of which are firmly secured four horizontal bundles of fine brass wire; above it is a vessel C, containing stale beer, which is allowed to drop constantly, by the pipe and tap D, upon the revolving brushes whilst working; the sides E E are to prevent splashing, and the tray F, and pipe G, are to collect and remove the waste liquid. The workman stands opposite the end of the machine in using it, working the treadle with his foot, and pressing the article against the ends of

the revolving wire brushes, exposing in succession different parts of the article to their action. Wire of different degrees of fineness is used with different articles.

Fig. 85



81. *Connecting Wires.*—The depositor should provide a large number (several pounds weight) of pieces of copper wire, of about the size No. 18 or 20, of the Birmingham brass wire gauge, and about fifteen or twenty inches long, for suspending the smaller and more numerous articles to be coated in the depositing solutions; a few other pieces of a larger and stronger kind should be provided for the heavier articles. Copper is the most suitable metal for connecting-wires, and the most generally used, because it is one of the best conductors of electricity, being also flexible and not expensive; next to it we should select brass: silver is the best conductor, but is too expensive.

82. *Dipping Liquids, Pickling Liquids, &c.*—The depositor will next prepare his various liquids for cleansing articles for plating. For cleaning iron articles he will require large stoneware pans and jars, containing a mixture of one part of sulphuric acid, and twenty parts of water; a weaker solution may be used for some kinds of metal; smooth wrought-iron requires a weaker liquid than rough cast-iron. For cleaning either copper, brass, or German silver, he will require several stoneware pans, one containing strong nitric acid, another filled with "dipping" liquid (a mixture of 64 parts of water, 64 parts sulphuric acid, 32 parts nitric acid, and 1 part of hydrochloric acid), and a third containing "spent" liquid, *i.e.*, either nitric acid or dipping liquid, the power of which has been partly exhausted. In addition to these, he will require some glass-cutters' fine sand; with several small hand-brushes and pieces of old cloth, for brushing and rubbing the sand upon the more rusty and refractory parts of the metals to be cleaned; also a file and scraper to further assist in cleaning them. Hydrofluoric acid, contained in a small leaden or gutta-percha bottle, should be at hand, to apply to the "glazed" patches occasionally met with upon cast-iron.

83. *Battery Liquids.*—The only kind of acid used by electro-platers, to excite their batteries, is sulphuric acid. For the negative solution of Daniell's batteries, a stock of sulphate of copper should be provided.

84. *Liquids for Causing Adhesive Deposits.*—Solutions of nitrate, or of cyanide of mercury, will be required for preparing the surfaces of copper, brass, and German silver, for receiving adhesive deposits of silver. The nitrate solution is prepared by adding one ounce of mercury to sufficient nitric acid, diluted with three times its bulk of distilled water to dissolve it: no more mercury must be added than the liquid will dissolve: when thoroughly dissolved, dilute it with about one gallon of water. To prepare the cyanide solution, dissolve one ounce of mercury as stated, dilute it with water, and add a solution of cyanide of potassium to it, just as long as a precipitate is produced; filter it, add a small quantity of water to the precipitate in the filter, and, when thoroughly drained, take out the precipitate, and add to it a strong solution of cyanide of potassium until it is all dissolved; then add a little more cyanide solution, and finally dilute it with water until the whole measures one gallon. The solution, when prepared, is kept in a large stoneware pan, a pan of dipping liquid and another of water being near it, and each placed near the scratch-brush lathe and depositing-vats in the silvering-room.

85. *Materials for Moulding.*—The electro-depositor who includes in his business not only the ordinary electroplating, but also the manufacture of works of art by deposition, requires a number of substances for moulding, and preparing the surface of the moulds to receive a deposit. For moulding ordinary metal objects, he often uses gutta-percha or a composition consisting of equal parts of white wax and spermaceti; but one of the best substances we have used for this purpose, has been a composition of our own, consisting of two parts of gutta-percha, and one part of Jeffery's marine glue: the glue is cut up into small pieces, and melted at a gentle heat in an iron ladle; the gutta-percha, also cut very small, is then added, and the mixture constantly and vigorously stirred at a gentle heat until the two are thoroughly incorporated. This substance possesses several important advantages over gutta-percha alone as a moulding material; it is softer when heated, and takes a sharper impression; it contracts more in cooling, and is therefore more easily removed from the original; and in taking the blacklead it is very superior to gutta-percha. With ordinary care many copies may be taken by deposition off one of these moulds; we have taken upwards of ten from one of them.

86. *Elastic Moulding Composition.*—When the objects to be copied are much under-cut, or when we wish to take a mould of a bust all in one piece, elastic moulding composition is required. The best substance of this kind, and almost the only one used, is composed of four parts of best Russian glue and one part of treacle; the glue is broken into small pieces, and soaked for one or two hours, or until it is quite soft, in sufficient *cold* water to cover it; when it is soft the superfluous water is thrown away, and the glue, together with the treacle, is heated in a common glue-pot, like ordinary glue, to nearly a boiling heat, and stirred until the two substances are thoroughly mixed: the use of the treacle is to prevent the mould drying and shrinking too rapidly.

87. *Blacklead, Phosphorus, Liquid, &c.*—For rendering the surfaces of non-conducting substances, such as gutta-percha, wax, marine glue, &c., conductible, the following substances are used:—

1st. The common powder blacklead for ordinary non-elastic moulds: there is the greatest difference, however, between various specimens of blacklead in their value for this purpose, some causing the deposit to spread over the moulds very quickly, whilst others scarcely cause it to spread at all; the best we have found, and it has been very good, is "Dix's," sold in twopenny packets, one or two of which will serve the operator a long time for this purpose.

2nd. For moulds of elastic composition (86), the depositor will require the following liquids, patented by Mr. Alexander Parkes:—A, the phosphorus solution: to make nearly three ounces of which, melt 64 grains of bees-wax or tallow; then dissolve eight grains of india-rubber cut up very small, in 160 grains of bisulphide of carbon; and when it is dissolved, add to it very carefully (as it is highly inflammable) the melted wax, and shake the mixture thoroughly. Then dissolve 64 grains of phosphorus in 960 grains (about 2¼ ounces) of bisulphide of carbon, and add to it 80 grains of spirit of turpentine, and 64 grains of asphalte in fine powder: when dissolved, add this solution to the previous one of india-rubber and wax, and thoroughly mix them by shaking. B, the silver solution: to make twenty ounces (one pint) of this liquid, dissolve about 18 or 19 grains of pure silver in about 20 or 25 grains of the strongest nitric acid, and then dilute it to the required volume with *distilled* water. And C, the gold solution: to make twenty ounces of which, dissolve about 5 or 6 grains of pure gold in about 20 or 25 grains of a hot mixture of one measure of nitric acid, and about two or three measures of hydrochloric acid; when dissolved, dilute the solution with 20 ounces of *distilled* water.

The same patentee includes in his patent a phosphorus moulding composition, by the use of which the immersion in the phosphorus solution is dispensed with, the moulds themselves containing the required amount of phosphorus. To make about one pound of this composition, melt together half a pound each of wax and deers' fat; then dissolve about 19 or 20 grains of phosphorus in about 300 grains of bisulphide of carbon; keep the wax mixture barely melted, and add the phosphorus solution slowly to it, and with brisk stirring of the fat, pouring it in at the bottom of the melted mixture by a vessel with a long spout, to prevent its inflaming. It is highly dangerous to have split portions of the phosphorus composition where it can come in contact with wood, paper, rags, &c., as, after a lapse of some time (even hours), they will often burst into flame.

88. *Selection of Depositing Processes.*—For very small articles, of which there are a great number, such as buttons, hooks-and-eyes, pins, &c., and which require only a very thin deposit, the simple immersion or wash process will answer very well, being both easy of execution and cheap. For the multiplication of numerous small articles in copper, such as medallions, &c., the single cell process is very advantageous; it is quicker than the battery process; and considering the time occupied, and the other elements of expense, it is to be preferred to that method. But for all ordinary deposits, plating, &c., the battery process is by far the best, because coatings of any thickness, in all ordinary metals, may be obtained by it, and the solutions do not, as in other processes, require renewal.

89. *Methods of Making Depositing Solutions.*—The operator will next consider about making depositing liquids. This may be done by two methods; the one called the chemical, and the other the battery process. The chemical process consists in mixing the various ingredients by the usual means, and in suitable proportions to form the liquids: for instance—1st, the ordinary sulphate of copper solution is prepared by dissolving a certain proportion of commercial sulphate of copper in water, and adding to it a definite quantity of sulphuric acid to afford *free* acid; and, 2nd, to form the ordinary cyanide of silver and potassium plating liquid, silver is dissolved in dilute nitric acid; the solution of nitrate of silver formed is precipitated by addition of a solution of cyanide of potassium; the white precipitate of cyanide of silver is washed, and then added, as much of it as will dissolve, to a solution of cyanide of potassium; after that, an additional portion of cyanide of potassium is added to afford *free* cyanide. The battery process consists in taking some water, and dissolving in it a certain proportion of acid or salt, as the case may be; then placing a large anode of the given metal at the lower part of the liquid, and a small bright cathode at the upper part, and, if necessary, applying heat. Connection is to be made with a suitable battery until the required quantity of metal is dissolved, which is indicated by the cathode receiving a good deposit: in making gold solutions the cathode is generally placed in a small porous cell filled with the same liquid, and immersed nearly to its edge in the outer liquid; and by transferring the cathode occasionally to the gold solution, and observing if it receive a good deposit, we may know that sufficient metal is dissolved; the liquid of the cell may then be added to the outer solution. If it be wished to make sulphate of copper solution by this method (which we should not advise, however, the salt being so cheap), take the same quantity of water as we prescribed for the chemical method, and add to it as much acid as was contained in the salt of copper with the free acid as before, and then pass a current from a battery of one or two pairs by a large anode and small cathode, until sufficient metal is dissolved; or if it be desired to make some cyanide of silver and potassium solution by this method, which is sometimes done, take the same proportions of water, cyanide of potassium, and free cyanide as in the chemical process, and pass the electric current by a large silver anode, until the same proportion of silver is dissolved as required by the chemical method.

90. *Selection of Depositing Liquids.*—The following rules should be observed in selecting a suitable depositing liquid for the battery process.

1st. It should act strongly upon the anode, and hold abundance of metal in solution.

2nd. It should possess good electrical conducting power.

3rd. It should yield its metal freely, and in a reguline state.

4th. It should not act chemically to any great extent upon the base metals, because it is those that we generally wish to coat, and chemical action upon them would endanger the adhesion of the deposited metal.

5th. It should not decompose by contact with the atmosphere, nor should light influence it in such a way as to injure it for depositing purposes.

6th. It is better if it do not evolve gas at the surface of the receiving article whilst depositing, because that generally indicates a waste of battery power, attended by oxidation of the liquid.

91. *Testing a Depositing Liquid.*—To test a depositing liquid, pass a current of electricity through it, from about two pairs of Smee's batteries, with a suitable clean anode of proper size, and a clean piece of iron, brass, or copper, of about the same size, to receive a deposit, observing how much gas is evolved in the battery; if the deposit appear quickly, and of a bright and proper colour; and if it adhere to the metal, the cathode evolving gas from its surface, and the anode dissolving freely, cleanly, and without escape of gas, work it at intervals, keeping it exposed to light and air; observe if it continue to work well, or whether, on the contrary, it shows a decrease of conductibility, deposits a sediment, or if the anode become covered with an insoluble crust (this last may arise either from deficiency of free acid, or from impurities in the metal). If but little gas be evolved in the battery, the liquid in the cell is a bad conductor, and will neither dissolve nor deposit the metal freely at that temperature, or it is deficient in *free* acid or *free* salt. If the deposited metal be of a bad colour, either the battery is too strong, the receiving article too small, or the liquid is incapable of yielding good metal. If the immersed metal or article be coated by simple immersion without the aid of the battery, it shows that, to adapt the liquid to articles made of that particular metal or alloy, they must receive some previous preparation, in order to make the deposit adhere. If it deposit a sediment, or alter in conductibility by exposure to air and light, the probability is that those influences alter either its chemical composition, or the arrangement of its particles. If it evolve gas at the receiving surface during deposition, it shows either that there is too much battery power, too little metal in solution, too much *free* acid, or that it is a wasteful liquid, in which one part only of the current is employed in depositing metal, whilst another part of it is employed in evolving gas and oxidating the liquid.

92. *Testing Solutions for Depositing Alloys.*—With solutions in which alloys are to be deposited, the most important condition is, that neither of the metals to be deposited should be electro-positive to each other in that liquid. This is best tested by taking a wire of each metal, connecting them with a galvanometer, and simultaneously immersing their free ends in the liquid; if either be electro-positive, the needles of the instrument will be deflected, and the direction of the deflection will indicate which is positive, while the amount of deflection will indicate the amount of their electric difference in that liquid. It may also be tested by immersing a wire of each metal (not in mutual contact)

in the liquid; if either become coated with metal in an hour, that one is positive; but if neither become coated in six hours, there is no perceptible electric difference between them.

93. The following experiments bear upon this part of the subject, and show that if a liquid contain two metals in solution, and a wire or other piece of each of those metals be immersed in the liquid, and one becomes covered with a deposit of metal, while the other does not, the one so covered is electro-positive to the other in that liquid, and the solution will only yield the same metal which is deposited by simple immersion.

Experiment 51.—With an alloy solution consisting of equal measures of a strong solution of protochloride of tin, and terchloride of antimony, with an anode either of tin or antimony (the latter is the most proper, because it does not coat itself by simple immersion in the liquid), a copper cathode, and two small cells of Smee's battery, only antimony was deposited; tin coated itself with antimony in this solution by simple immersion, and was found by the galvanometer to be strongly positive to that metal.

Experiment 52.—With a liquid composed of equal measures of a solution of protochloride of tin and chloride of bismuth, and either a bismuth or tin anode (the former is the best), a brass cathode, and two cells of Smee's battery, only bismuth was deposited; tin was positive to bismuth in this liquid by the galvanometer, and coated itself quickly with that metal by simple immersion.

Experiment 53.—With a mixture of equal measures of terchloride of antimony, and chloride of bismuth, antimony anode, copper cathode, and a feeble Smee's battery, only antimony was deposited; bismuth coated itself slowly with the antimony in solution by simple immersion, and was found by the galvanometer to be moderately positive to the latter metal.

Experiment 54.—With 100 grains each of protochloride of tin and chloride of zinc dissolved together in an ounce of distilled water, tin anode, copper cathode, and one cell of Smee's battery, only tin was deposited; zinc was positive to tin in this liquid by the galvanometer, and deposited tin upon itself by simple immersion.

Experiment 55.—With equal measures of strong solutions of nitrate of zinc, and ternitrate of bismuth, and a little nitric acid, bismuth anode, copper cathode, and a feeble one-pair battery, only bismuth was deposited; zinc was strongly positive to bismuth in this liquid by the galvanometer, and coated itself quickly with that metal by simple immersion.

Experiment 56.—With a solution of the mixed sulphates of zinc and copper, copper anode and cathode, and a single small battery, copper alone was deposited; zinc was strongly positive to copper in this liquid by the galvanometer, and coated itself immediately with copper in it by simple immersion.

94. Further, if we take some distilled water, and caustic potash be dissolved in it, on passing a moderately strong current through it by platina electrodes, hydrogen gas will alone be set free at the cathode: in this case, also, hydrogen—the least positive of the two positive elements of the liquid—potassium and hydrogen—is set free or deposited. If we now add a little sulphuric acid to the liquid to convert it into a solution of sulphate of potash, with some sulphate of zinc besides, and pass a weak current through, we shall obtain a deposit of zinc on the cathode, but no hydrogen or potassium: in this case we cannot determine by the galvanometer which is the most positive in this liquid, hydrogen or zinc, because the former is a gas; but it is probable that hydrogen is the most positive, because zinc does not evolve it by simple immersion in this liquid. If we further add to the liquid a small quantity of sulphate of copper, and treat it as before, neither potassium, hydrogen, nor zinc will be deposited, but only copper; and we find by the galvanometer, that copper is less positive than zinc in such a liquid, and that zinc coats itself with copper in it by simple immersion: in this case, also, the least positive of the positive elements of the liquid is alone deposited. From these and many other experiments, which we have tried with similar results, we deduce the following rule:—If a liquid contain several metals or other electro-positive substances dissolved, and a *weak* electric current be passed through it, only that substance which is the least electro-positive will be deposited.

95. With regard to the influence exercised by the proportions of the ingredients of the liquid, and the strength of the current, we may observe, that, if a liquid contain several metals dissolved in equal quantities, and only one is being deposited by the passage of a weak current, a considerable increase in the strength of the current will cause a portion of the next more positive metal to be deposited along with the less positive one; but this alloy deposit will not be very coherent, because the power required to deposit the second metal in the reguline state will be so great as to deposit the first as a soft powder. This holds most true when the difference of electric power required is at a maximum. For instance—1st. If small and equal quantities of sulphate of zinc and sulphate of copper are dissolved together in a large quantity of water, and a feeble current be passed through the solution, only reguline copper will be deposited; but if the battery power be considerably increased, either by a greater number or larger surface of the battery plates, the deposit of copper will cease to be reguline, and zinc will be deposited with it. If the power be still further increased, hydrogen gas will also be evolved at the surface of the deposited metals. 2nd. If we dissolve a small quantity of sulphate of copper, and a great quantity of sulphate of zinc, in a large quantity of water, and pass a strong current through the solution, copper, zinc, and hydrogen will be set free at the cathode. 3rd. If we slightly moisten a lump of caustic potash with pure water, and pass a weak electric current through it by platina electrodes, hydrogen alone will be set free at the cathode; but if a very powerful current be employed, potassium also will be deposited. In each of these cases we find, that when the current is weak, the least positive of the positive substances is alone deposited; but if the power be sufficiently increased, and there is only a small proportion of the less positive substance present, the more positive substances, even though they are much more positive, will also be deposited. Thus the weaker affinities are overcome first, and to the greatest extent; the current of electricity exercising its influence first, and in the greatest proportions, upon the salt of the least positive metals.

96. *Depositing Liquids.*—For the benefit of the practical depositor, to whom a general knowledge of all solutions from which ordinary metals may be deposited, with their respective advantages and disadvantages, is of considerable importance, we will give a description of those solutions in regular order, making such remarks in our progress as will be likely to assist him in the selection of those most suitable for his particular purposes.

97. *Antimony Solutions.*—The most common salts of antimony are the sulphide, terchloride, and potassio-tartrate. The hydrochlorate of terchloride of antimony, i.e., the ordinary chloride or butter of antimony, as prepared for pharmaceutical purposes, is formed thus:—Take one pound of black sulphide of antimony; add to it four pints of hydrochloric acid; gently heat the mixture with constant stirring, until the gas evolved decreases; then boil it slowly down to two pints, keeping it partly covered all the time; cool, and filter through calico, and keep it in a stoppered bottle. It is a yellowish-red liquid, of specific gravity 1·47, but becomes nearly colourless by depositing antimony by the battery process.

A similar solution may be made by the battery method; this consists in passing a current from several pairs of batteries through strong hydrochloric acid by a large anode of antimony, until a good deposit is obtained: this solution is nearly colourless. The chloride of antimony is an excellent conductor of electricity; it dissolves the anode freely; yields plenty of bright reguline metal if the battery power be sufficiently weak; and its depositing power does not deteriorate by exposure to light or the atmosphere, but it appears to be gradually exhausted by working; it is also decomposed more or less rapidly by zinc, tin, lead, iron, brass, copper, and German silver, each of which coat themselves in it with antimony by simple immersion; and articles immersed in it require to be washed with hydrochloric acid before washing them with water, otherwise the latter decomposes the adhering liquid, and covers them with a white insoluble powder.

98. The mixed chlorides of antimony and ammonia form a very good depositing liquid. It may be produced either by the battery process, by mixing one measure of a saturated solution of sal-ammoniac with one measure of hydrochloric acid, and working antimony into it by means of a battery and a large antimony anode; or by simply mixing together equal measures of a saturated solution of sal-ammoniac and commercial chloride of antimony. This solution conducts easily, yields its metal freely and of good quality, and does not act so strongly upon base metals as chloride of antimony alone; but in other respects it is similar to the chloride. The mixed chlorides of antimony and manganese, or of antimony and bismuth, yield a reguline deposit easily, but do not appear to possess any special advantages.

99. The potassio-tartrate of antimony is a salt not very soluble in water; its aqueous solution is a very bad conductor of electricity, and is not to be compared to the chloride for depositing purposes. We have never been able, either with strong or weak batteries, to deposit from it anything better than a small quantity of antimony in the state of a perfectly black powder: on the other hand, its solution in hydrochloric acid (which dissolves it very freely), or hydrochloric acid and water, is by far the best that we have tried for depositing antimony: it is an excellent conductor of electricity; it is not impaired by long working or exposure to light or the atmosphere (we have deposited antimony from it constantly during many months); it will bear a great amount of battery power without the deposit passing into the state of a loose powder; it deposits reguline metal very rapidly and in great thickness. We have obtained such deposits from it upwards of two inches in thickness; articles immersed in it wash clean in water alone, without the previous use of hydrochloric acid. It may be made by mixing together about two pounds of water, four pounds of hydrochloric acid, and eight pounds of potassio-tartrate of antimony; a greater proportion of water may be used if desired.

100. Both the black and red sulphides of antimony dissolve in cold hydro-sulphate of ammonia, and the resulting solutions conduct very freely with an antimony anode and one cell of Smee's battery, but yield no deposit of metal even with a battery of twenty-five cells' intensity. Aqueous solutions either of caustic potash, tartrate of potash, or oxalate of potash, scarcely conduct at all with an anode of antimony, and a battery consisting of one or two cells. Cyanide of antimony, dissolved in a solution of cyanide of potassium, has been proposed as a depositing liquid; but we have found a solution of cyanide of potassium to be a very bad conductor with an anode of antimony.

101. Antimony is one of the easiest metals to deposit in the reguline state; its appearance when deposited from the chloride solutions, and from the solution of the potassio-tartrate in hydrochloric acid, is very beautiful; and when deposited slowly, it has much of the lustre of highly-polished steel. Some of its properties when thus deposited are very peculiar and interesting, especially with regard to heat. If, during any part of the time the deposit is progressing, the deposited antimony be taken out and struck gently, or rubbed with any hard substance, such as metal or glass, an explosion will occur, accompanied with a small cloud of white vapour—sometimes with a flash of light, and nearly always with considerable heat, sufficient to burn the fingers, melt gutta-percha, burn paper and even scorch deal wood to a brown colour, especially if the deposit be thick. This is invariably accompanied by fracture of the deposited metal; sometimes, when the process of deposition has been interrupted, and the deposited metal is not homogeneous, the fracture extends through the metal to upwards of one-eighth of an inch in depth. This phenomenon has been observed many times, both before and since its first publication; in several instances the explosion was produced even in the liquid, by striking the deposit against the glass vessel which contained it; and in one instance it occurred after the metal had been well washed with dilute hydrochloric acid, dried, and had remained out of the liquid several hours.

On one occasion, a deposit had been well washed, dried, and out of the solution many hours; and a friend, in course of conversation, was unconsciously breaking small portions off it with his fingers, when it became suddenly heated, and exploded, causing a slight noise like the lighting of a congreve match, and burning his fingers. In other cases, a deposit has been progressing, and has been removed an instant for examination, and the battery liquid strengthened by the addition of acid: upon examining the deposit a few hours afterwards, it has been found cracked in various directions, as if an explosion had occurred in the interval, although the apparatus had been undisturbed. A French writer has suggested that this deposit is a compound of antimony and hydrogen; and from the fact that the explosions occurred when the metal was depositing rather rapidly, we are inclined to think his explanation correct; the extra power, as we have seen in other cases (94, 95), causing hydrogen deposit, which, in its nascent state, instead of being evolved, might combine with the metal and form an explosive compound. Another suggestion we would make is, that the metal may be deposited in a peculiar condition of unequal mechanical tension, similar to that of unannealed glass, and that, by breaking, the closer aggregation of the particles may develop light and heat.

102. Another peculiarity in depositing antimony from the potassio-tartrate solution is, that if the solution be a very dense one, and the process long continued without disturbance of the liquid, the deposit occurring upon the cathode will slowly spread out in the form of a thin sheet upon the surface of the liquid, until it touches the anode; whilst the deposit beneath progresses very slowly. We have a button of antimony formed in this way upon a vertical copper wire, one and five-eighths inches in diameter, the deposit beneath the surface of the liquid having been only half an inch thick; it occupied about eighteen days, with a small cell of Smee's battery, in forming. Deposits of antimony formed in the above solution do not spread over blackleaded surfaces of gutta-percha, nor do they adhere with any great degree of firmness to copper, brass, or iron.

103. *Bismuth Salts.*—The most usual compounds of bismuth are the chloride, mononitrate (pearl white), and ternitrate. The chloride is formed by digesting bismuth filings a long time in a warm place with hydrochloric acid. The mononitrate is formed by dissolving bismuth to saturation in warm dilute nitric acid, and then adding a large quantity, say fifty or a hundred times its volume, of water; the precipitate produced, when well washed with water, is the substance required. The ternitrate is formed by dissolving the metal in hot nitric acid, evaporating the solution, and leaving it in a cold place to crystallise. Bismuth may easily be deposited from a solution formed by dissolving either mononitrate or ternitrate of bismuth in dilute nitric acid, but it requires an exceedingly feeble current to deposit it in a reguline state; its appearance when so deposited is very beautiful—white with a faint pinkish tint, and with a fine silky lustre; it does not spread over black-leaded surfaces of gutta-percha in this liquid. A bismuth anode does not dissolve readily in a hot solution of cyanide of potassium.

104. *Zinc Salts.*—There are a variety of salts of this metal in ordinary use, the most common of which are

the sulphate, chloride, nitrate, and acetate. The sulphate may be formed by dissolving zinc to saturation in a mixture of sulphuric acid and water, filtering and evaporating the liquid, and setting it in a cold place to crystallise. The chloride is formed by saturating hydrochloric acid with zinc, filtering, evaporating, and crystallising. The acetate may be made either by dissolving zinc in strong acetic acid to saturation, then evaporating and crystallising the solution; or by adding a solution of acetate of lead to a solution of sulphate of zinc as long as it produces a precipitate; then filter, evaporate, and crystallise the liquid.

105. *Zinc Solution.*—The sulphate of zinc solution for depositing may be formed by dissolving two pounds of the salt in a gallon of water, and filtering the mixture; but the best sulphate depositing solution we have used has been the spent liquid taken from a cell of a Smee's battery, in which there had occurred a very good deposit of zinc upon the platinised silver plate; but with this and other solutions of zinc there is a great tendency to the evolution of hydrogen gas at the cathode during deposition; they require, therefore, to be worked very carefully, and with very feeble battery power. Zinc may be readily deposited, either by the single cell, or by the battery process, from a neutral solution of the sulphate; but the single cell is less adapted for its deposition than the battery, because the acid, set free by the deposition of the metal, reacts upon the deposit, and diminishes its cohesion. The other solutions, such as the chloride, nitrate, acetate, or the various double salts of zinc, with ammonia, or potash, do not appear to possess any general advantages over the sulphate.

Amongst other liquids, that of cyanide of zinc dissolved in a solution of cyanide of potassium, has been recommended; but it is a bad conductor with a zinc anode, and requires to be used hot to make it conduct at all freely, or make the anode dissolve. This might easily have been foreseen from a knowledge of the fact, that the affinity of cyanogen for all, or nearly all, the base metals is comparatively feeble. We have found by experiment, that a solution of cyanide of potassium will dissolve only about one-half as much cyanide of zinc as it will of cyanide of copper. Zinc oxide dissolves somewhat freely in a boiling solution of cyanide of potassium. Cyanide of zinc dissolves freely in a solution of sesquicarbonate of ammonia. Ferro-cyanide of zinc is but feebly soluble in a boiling solution either of ferro-cyanide (yellow prussiate) or of ferri-cyanide (red prussiate) of potassium, but it is freely soluble in a boiling solution of cyanide of potassium. Zinc deposits spread over blackleaded surfaces by the battery process, in the same manner as copper.

106. *Cadmium Solution.*—A patent was taken out, March 19th, 1849, by Messrs. Russell and Woolrich, for the electro-deposition of cadmium; and the following is their description of the process:—"Take cadmium and dissolve it in nitric acid diluted with five or six times its bulk of water, at a temperature of about 80° or 100° Fah., adding the dilute acid by degrees until the metal is all dissolved; to this solution of cadmium a solution of carbonate of soda (made by dissolving one pound of the ordinary crystals of soda in one gallon of water) is to be added until the cadmium is all precipitated; the precipitate thus obtained is to be washed four or five times with tepid water; next add as much of a solution of cyanide of potassium as will dissolve the precipitate; after which, one-tenth more of the solution of cyanide of potassium is to be added, to form *free* cyanide. The strength of this solution may vary; but the patentees prefer a solution containing six troy ounces of metal to the gallon. The solution is worked at about 100° Fah., with a plate of cadmium as an anode."

107. *Tin Salts.*—The most common salts of tin are the peroxide and protochloride: in addition to these there are two others, used extensively in Manchester, and the cotton-printing districts—viz., the bichloride and the stannate of soda, *i.e.*, oxide of tin combined with caustic soda. Peroxide of tin is formed by dissolving protochloride of tin in water containing a few drops of hydrochloric acid, and then adding liquid ammonia, or a solution of carbonate of potash, as long as a precipitate can be produced; the precipitated peroxide of tin should be washed and dried. Protochloride of tin is easily made by adding grain tin to strong hydrochloric acid, and keeping it at 150° or 200° Fah., until gas ceases to be evolved from the metal; the resulting solution should then be evaporated and crystallised. Aqueous bichloride of tin may be made by dissolving tin in aqua regia not containing too much nitric acid; a mixture of nitric acid with sal-ammoniac or common salt may likewise be used. Stannate of potash may be formed by fusing together one equivalent (75 parts) of freshly precipitated peroxide of tin, and one equivalent either of caustic potass (56·2 parts), or of crystallised carbonate of potash (87·2 parts).

108. *Tin Solutions.*—M. Roseleur has patented the following liquids for the deposition of tin:—

1st. For simple immersion or wash process, which may be used for small articles generally—dissolve 17½ ounces of ammoniacal alum in 22 pounds of boiling water, and, when dissolved, add one ounce of protochloride of tin: the articles to be coated should be well cleaned, and then immersed in the liquid, and moved about in it until they are sufficiently white.

2nd. For depositing tin upon lead, iron, steel, copper, or brass, by connecting the articles with a piece of zinc, and immersing them in the solution—dissolve 10½ ounces of bitartrate of potash in 17½ pints of water; then add three-quarters of an ounce of protochloride of tin, and boil it a few minutes: the articles to be coated are immersed in the solution in contact with a piece of zinc of proportionate size.

3rd. For coating zinc, iron, copper, and many other metals by the battery process—dissolve 11 ounces of pyrophosphate of potash or soda in 17½ pounds of water; then add 4½ ounces of protochloride of tin, and operate by the battery process with an anode of tin. By this process, M. Roseleur states that he can tin metals beautifully and to any thickness. Pyrophosphate of soda is easily formed by heating to redness the common diphosphate of soda.

109. A protochloride of tin depositing liquid, may easily be formed by dissolving the ordinary commercial protochloride in water, and adding a little hydrochloric acid to remove any cloudiness or white precipitate which may be formed; a similar liquid may be made by the battery process, by passing a current through dilute hydrochloric acid by means of a large tin anode, until sufficient metal is dissolved. This or any other chloride of tin is not a good solution to obtain reguline metal from; it has a very great tendency to deposit the tin in the form of long crystalline needles, of a fernlike appearance, which often project from the corners and edges of the cathode to a distance of upwards of half an inch. A solution composed of eleven ounces of water, one ounce of hydrochloric acid, and eighty grains of protochloride of tin, admits of this effect being produced in a striking degree: nearly all the compounds of tin, and especially those formed with mineral acids, exhibit this tendency in a greater or less degree when acted upon by electrolysis, rendering the deposition of tin in thick layers of fine white coherent metal a matter of considerable difficulty.

110. The stannate of potash solution is easily formed either by dissolving the crystallised salt in water, or by dissolving freshly precipitated peroxide of tin (109), whilst still moist, in a boiling solution of caustic potash. It may also be easily formed by the battery process, by passing a strong current of electricity, by a large tin anode, through a strong and boiling solution of caustic potash, until the immersed cathode receives a free white deposit. This solution, if worked at 150° Fah., yields a good deposit of fine white metal; but it decomposes by exposure to the atmosphere, and soon deposits all its metal as oxide of tin. A solution of cyanide of potassium and tin has been proposed as a depositing liquid; but it is a bad conductor with a tin anode, even if hot, and does not dissolve the metal freely.

111. Mr. Joseph Steele coats zinc, iron, steel, copper, and brass, with tin, in his patent solution, by the battery process, thus:—Dissolve 60 pounds of common soda, 15 pounds of pearl-ash, 5 pounds of caustic potash, and 2 ounces of cyanide of potassium, in 75 gallons of water, at 75° Fah., and filter the mixture so made; then add 2 ounces of acetate of zinc, and 16 pounds of binoxide of tin; stir the resulting solution until all is dissolved; it is then ready for use. Work it by the battery process with an anode of zinc or tin, and with the liquid at 75° Fah.

112. *Electrical Relations of Tin and Iron.*—Tin is feebly negative to iron at all temperatures between 62° and 203° Fah. in distilled water, and positive to it at 212° Fah. It is positive to iron at all temperatures between 62° and 212° Fah. in a saturated solution of boracic acid; also the same between those temperatures in a strong solution of phosphoric acid in distilled water; or in one measure of oil of vitriol mixed with either nine or ninety-six measures of distilled water; or in a mixture of one measure of this acid, and 192 measures of distilled water, from 73° to 158° Fah., and negative to iron above that to 212° Fah. It is positive to iron from 72° to 212° Fah. in a mixture of equal measures of hydrochloric acid and water; it is negative to iron from 70° to 77° Fah., and positive above that to 212° Fah., in a mixture of one measure of hydrochloric acid and nine measures of distilled water; it is negative to iron from 70° to 212° Fah. in a mixture of one measure of hydrochloric acid, and ninety measures of distilled water; and positive to iron from 68° to 212° Fah. in one measure of hydrofluoric acid and nine measures of water; it is positive to iron in one measure of nitric acid and nine measures of water from 70° to 111° Fah., and negative from 111° to 212° Fah.; and it is positive to iron from 82° to 212° Fah. in a mixture of one measure of nitric acid and ninety-six measures of water.

113. *Lead Salts.*—The most common salts of lead are the nitrate, and the acetate. The nitrate is formed by dissolving lead in dilute nitric acid, taking care that no more lead is added than the acid will dissolve; the resulting solution must be filtered, evaporated, and crystallised; it is a hard, white salt, soluble in water. Acetate of lead is made by digesting oxide of lead in vinegar or acetic acid; filtering, evaporating, and crystallising the liquid: it is soluble in water.

114. *Lead Solution.*—Lead may be deposited from an aqueous solution, either of nitrate or acetate of lead, or from a solution of plumbite of potash: the latter is formed by dissolving litharge in a boiling solution of caustic potash. Zinc and tin articles (but not iron) decompose this liquid, and coat themselves with lead in it, by simple immersion. It is difficult to deposit any considerable thickness of reguline metal from either of these liquids.

115. *Salts of Iron.*—Among the salts of iron in most common use, are the sulphate, chloride, and nitrate: they may be respectively formed by dissolving metallic iron in dilute sulphuric, hydrochloric, or nitric acids, evaporating and crystallising the solution as much as possible out of contact with the atmosphere.

116. *Iron Solutions.*—Iron may be reduced from a solution of its protosulphate (green copperas), made by dissolving metallic iron in dilute sulphuric acid; or from its protochloride, which is preferable, and which is made by dissolving iron in hydrochloric acid. We have deposited it in the state of reguline white metal, by passing a current of considerable intensity (15 or 20 pairs) for one hour, through an anode of iron immersed in a saturated aqueous solution of sal-ammoniac; its appearance when deposited from this liquid is rather white, and very similar to that of freshly broken cast-iron. By the same means it may also be deposited, using a saturated solution, either of carbonate of ammonia, acetate of ammonia, or acetate of potash. Good metal may be obtained from a saturated aqueous solution of a mixture of two parts of protosulphate of iron and one part of sal-ammoniac. We have deposited it from an aqueous solution of ferrate of potash, which may be formed either by igniting peroxide of iron (crocus) very strongly for some minutes with caustic potash and saltpetre. Or make a very strong solution of caustic potash, immerse it in a large iron or steel anode, and a small copper or platina cathode, and pass a strong current from fifteen or twenty pairs of Smee's batteries through it until it acquires a deep amethyst or purple colour; by that time the cathode will have obtained a coating of iron, which will be in the state of a dark powder if the power have been too great, or it will have the appearance of white cast-iron, or intermediate between that and the appearance of reguline deposited zinc, if the power have been sufficiently weak. This solution rapidly decomposes without any very apparent cause, becoming colourless, and depositing all its metal in the state of peroxide at the bottom of the vessel. Iron may be very easily deposited from its sulphate, thus:—Dissolve a little crystalline sulphate of iron in water, and add a few drops of sulphuric acid to the solution; one pair of Smee's batteries may be used to deposit the iron upon copper or brass. The metal in this pure state has a very bright and beautiful silvery appearance. An aqueous solution of cyanide of potassium is a very bad conductor with an iron anode, even if it be maintained hot.

117. *Cobalt Solution.*—A solution of protochloride of cobalt may be easily formed by digesting commercial brown oxide of cobalt in hot hydrochloric acid; it is a deep-blue liquid, but changes to a reddish-brown colour on the addition of water; by slow cooling, fine red crystals of the chloride may be obtained. We have not tried this liquid for electro-deposition.

118. *Nickel Solutions.*—The nitrate of nickel solution may be formed by dissolving nickel in nitric acid slightly diluted with water, and, when dissolved, diluting with additional water; it is a solution which does not yield its metal freely. We have deposited nickel in the state of reguline white metal, from a solution of the double chloride of nickel and ammonia, by making a lump of metallic nickel the anode in a strong aqueous solution of sal-ammoniac, and passing a strong current of electricity through it for several hours, until the liquid acquired a pale greenish-blue colour. We have also obtained a similar deposit by treating a solution of one part of arseniate of potash and five parts of water in a similar manner. It has also been deposited from a solution formed by dissolving pure nickel in nitric acid, then diluting and precipitating it by a solution of carbonate of potash, or cyanide of potassium; washing the precipitate, and dissolving it nearly to saturation, in a solution of cyanide of potassium, and operating upon this liquid, by the battery process, with an anode of pure metal. Its appearance, when deposited from this solution, is said to be nearly equal in whiteness to silver, and its deposition has been proposed to be applied to the production of an inferior class of plated articles.

119. *Copper Salts.*—The ordinary salts, &c., of copper, are the protoxide (black oxide of copper), sulphate, chloride, nitrate, acetate, and cyanide. To make the protoxide, heat either the carbonate or nitrate to a moderate red heat, or the sulphate to intense redness. The sulphate may be formed by heating one equivalent (31·7 parts) of copper filings, and at most two equivalents (98 parts) of oil of vitriol, until the residue is quite dry; then dissolving the product in water, filtering, evaporating, and crystallising the solution; but it is much more convenient to purchase it, on account of its low price. The chloride and nitrate may be formed—the first by dissolving copper in aqua regia, or by saturating hydrochloric acid with protoxide of copper, and evaporating and crystallising the liquids; and the second, by dissolving copper in nitric acid, evaporating and crystallising the solution. Acetate of copper is most conveniently purchased; its commercial name is crystallised verdigris. Cyanide of copper may be made by adding a solution of cyanide of potassium to a solution of sulphate of copper (each liquid being cold), as long as a precipitate can be produced—filtering and washing the precipitate, which is the required compound; it is a fine powder, of a pale-green colour. In the operation, a large quantity of

cyanogen gas is evolved, which, if freely inhaled, is dangerous to the health: in consequence, also, of this escape of cyanogen, the cyanide of copper is not a *proto*-cyanide, but contains two equivalents of cyanogen for every three equivalents of copper; it is freely soluble in a solution of cyanide of potassium; it is also soluble in aqueous ammonia and in a solution of carbonate of ammonia. The proportions of materials we have used in making it, have been 65 parts of cyanide of potassium, and 125 parts of sulphate of copper. The precipitating solution is invariably greenish-blue, and contains much dissolved copper after all precipitation ceases; but no use has hitherto been made of this remainder.

120. *Copper Solutions.*—Copper may be easily deposited either by simple immersion (wash process), by the single cell, or by the battery process. According to Reinsch, iron may be coated with a durable and polishable layer of copper of any thickness (?). The process by simple immersion is thus:—Mix together one measure of hydrochloric acid, three measures of water, and a few drops of a solution of sulphate of copper; clean and immerse the iron; wash it, rub it with the copper solution, and reimmerse it repeatedly, adding a few drops of the copper solution occasionally. In depositing copper by the single cell process, a nearly saturated solution of sulphate of copper answers very well; but for the battery process, an excellent solution may be made by dissolving four parts, by weight, of finely divided sulphate of copper (best quality), and one part of sulphuric acid, in about eighteen or twenty parts of water, and then filtering it; neither of these solutions, however, is fit to deposit copper upon iron, steel, or zinc; because the electrical relations of these metals in the solution are unsuitable: these metals decompose the solutions rapidly, and deposit the copper upon themselves by simple immersion. To effect an adhesive deposit of copper upon iron, a solution composed of cyanide of copper dissolved in a solution of cyanide of potassium may be used. It is formed thus:—Dissolve cyanide of copper to saturation in water containing about two pounds of cyanide of potassium to the gallon, and then add about one-eighth more of the cyanide of potassium solution to form *free* cyanide; the liquid is then ready, and should be used at a temperature of about 150° Fah.

121. Copper is electro-positive to iron in the following liquids at 60° Fah.:—Powerfully in a solution of hydrosulphuret of ammonia; feebly in a saturated solution of ammonia; in a solution of oxide of copper in liquid ammonia; in aqueous ammonia, or in a saturated solution of ferro-cyanide of potassium, each but for a short time; it then becomes negative. In a saturated solution of bichromate of potash; in a strong aqueous solution of sulphide of potassium, it is increasingly positive up to the boiling point of the liquid. This last liquid has a similar effect on brass.

122. *Brassing Solutions.*—Much interest and importance was long attached to the discovery of solutions whereby alloys, and especially brass, might be deposited in the reguline state, and various liquids have been used and patented for this purpose. M. de Ruolz, in 1841, deposited brass from the cyanides of zinc and copper, dissolved together in a solution of cyanide of potassium. Copper articles may be superficially brassed by boiling them in a solution of bitartrate of potash with zinc amalgam, or by boiling them in dilute hydrochloric acid with some bitartrate of potash and zinc amalgam.

123. The same object was effected by Russell and Woolrich's patent, dated March 19th, 1849; which is as follows:—Take 10 pounds of acetate of copper, 1 pound of acetate of zinc, 10 pounds of acetate of potash, and 5 gallons of hot water; dissolve the salts in the water, add as much of a solution of cyanide of potassium as will precipitate the mixture, and redissolve the precipitate; in addition, add about one-tenth of cyanide of potassium. Use a brass anode, or else two anodes—one of zinc and one of copper.

124. Joseph Steele's patent, dated August 9th, 1850.—Dissolve 2¼ pounds of American potash in 6 gallons of hot water, and filter the solution; also dissolve 2¼ ounces of acetate of copper in half a pint of strong liquid ammonia, and add it to the first solution with stirring; also add 4 or 5 ounces of sulphate of zinc, and stir till dissolved; and, finally, add 2 ounces of cyanide of potassium, filter the resulting solution, and use it at 100° Fah., with a brass anode. To obtain a dark-coloured brass add more acetate of copper; and to obtain it of a lighter colour, add more sulphate of zinc.

125. Salzede's patent, dated September 30th, 1847.—Take 5,000 parts of water, dissolve 12 parts of cyanide of potassium in 120 parts of it, then add 610 parts of sub-carbonate of potash, 48 parts of sulphate of zinc, and 25 parts of chloride of copper to the remainder of the water, and heat the mixture from 144° to 172° Fah.; and when the salts are entirely dissolved, add 305 parts of nitrate of ammonia, allow the liquid to remain undisturbed for twenty hours, and then add the solution of cyanide of potassium; allow it to remain again till clear, and then draw off the transparent liquid, which is ready for use; work it with a large brass anode and a strong battery. Another liquid which he uses for brassing, consists of 5,000 parts of water, 500 parts of sub-carbonate of potash, 35 parts of sulphate of zinc, 15 parts of chloride of copper, and 50 parts of cyanide of potassium. For a bronzing solution, he uses 25 parts of chloride of tin in place of the sulphate of zinc of the first brassing liquid, and proceeds as with that process; for a second bronzing solution, he uses 12 parts of chloride of tin in place of the sulphate of zinc of the second brassing liquid, using the solution from 77° to 97° Fah.

126. Brunel, Bisson, and Gaugain's formula consists of 50 parts of carbonate of potash, 2 parts of chloride of copper, 4 parts of sulphate of zinc, and 25 parts of nitrate of ammonia, dissolved together in cold water, which are used with a brass anode and a strong battery.

127. Morris and Johnson's patent, dated December 11th, 1852.—According to this patent, dissolve 1 pound of cyanide of potassium, 1 pound of commercial carbonate of ammonia, 2 ounces of cyanide of copper, and 1 ounce of cyanide of zinc, in 1 gallon of water, and use the solution at 150° Fah., with a large anode of brass and a powerful battery. Or a solution may be taken of 1 pound of cyanide of potassium and 1 pound of carbonate of ammonia, dissolved in 1 gallon of water, and saturated with copper and zinc to the requisite degree by means of a strong battery, a large brass anode, and small cathode, until the latter receives a good deposit of brass; the solution being at a temperature of 150° Fah. To increase the proportion of copper in the deposit, either add cyanide of potassium, or raise the temperature of the liquid; and to increase the proportion of zinc in it, either add carbonate of ammonia, or lower the temperature.

128. Of the numerous solutions that have been tried for depositing brass, the one just mentioned is much the best. By it, reguline and thick deposits of brass, of uniform colour, and of any desired composition, may be obtained. It is not an expensive liquid; it acts with average strength upon the anode; it holds a sufficient quantity of the alloy in solution; it conducts electricity with moderate facility; and it yields its metal in the reguline state very uniformly; it bears a great variation in the electric power without injury to the character of the deposit, and is, therefore, very easily managed; it does not act perceptibly upon cast-iron, wrought-iron, steel, or even zinc, so as to injure the adhesion of the deposit; and it is not decomposed by exposure to the atmosphere, to light, or heat, in such a way as to affect its depositing power. Its defects are, that it requires to be worked hot, and with considerable battery power, in order to make the anode dissolve rapidly, the solution conduct copiously, and to cause a rapid deposit; it also evolves an abundance of gas at the cathode when working, whether the solution be hot or cold, which indicates that part of the battery power is expended in decomposing the water of the liquid, depositing its hydrogen with the metallic alloy, and oxidising the solution.

But all the brassing solutions are, in a greater or less degree, imperfect.

Deposition of German Silver.—The same patentees also deposit German silver by the following process:—Dissolve 1 pound of cyanide of potassium and 1 pound of carbonate of ammonia in 1 gallon of water; heat the solution to 150° Fah.; immerse a large anode of German silver in the liquid, and a small cathode of any suitable metal; connect the two with a powerful battery, and pass the current of electricity until considerable metal is dissolved and a bright cathode receives a deposit of good colour: the solution is then ready for use.

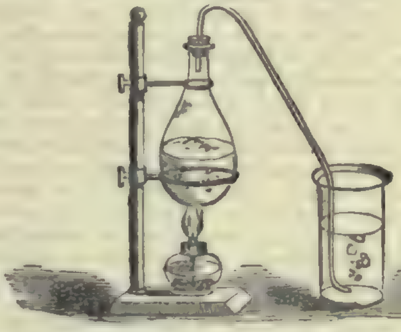
129. *Mercury Solutions.*—The ordinary compounds of mercury are the binoxide (red precipitate), bisulphide (vermilion), bichloride (corrosive sublimate), nitrate, and bicyanide. The nitrate is formed by dissolving mercury in nitric acid diluted with three times its bulk of water, the mixture being cold, and no more metal added than the acid will dissolve. The solution, when diluted with water, may be used for depositing by the battery process—a layer of mercury at the bottom of the liquid being used as the anode, and connected with the battery by a platina wire passing through a tube of glass or gutta-percha. The bicyanide is made by taking 8 parts of Prussian blue and 16 parts of peroxide of mercury, both in the state of fine powder, in 30 parts of water, boiling the mixture for about a quarter of an hour, filtering the liquid, and evaporating, and crystallising the solution; the resulting salt is the bicyanide; and to form it into a solution fit for depositing, it must be dissolved in a solution of cyanide of potassium: the solution may be used with a mercury anode and battery, as already described.

130. *Silver Salts.*—The most common salts, &c., of silver are the oxide, chloride, nitrate, and cyanide. Oxide of silver is prepared by adding a solution of caustic potash to a solution of nitrate of silver, as long as a precipitate can be produced, which is oxide of silver. Chloride of silver is made by adding either hydrochloric acid or a solution of common salt to a solution of nitrate of silver, until a precipitate ceases to be formed: the white precipitate of chloride of silver should be washed, dried, and preserved out of the influence of light. Nitrate of silver is easily formed by adding grain silver, in small quantities at a time, to a warm mixture of one measure of distilled water and four measures of the strongest nitric acid: if the liquid be too hot, or too much silver be added at a time, the action will be very strong, and loss of materials may be occasioned; in such a case add a small quantity of cold distilled water. When the liquid ceases to dissolve more metal, it should be evaporated and crystallised, or else kept protected from the light until required to be used: nearly all the compounds of silver are formed by means of this salt. Acetate of silver is made either by adding a solution of acetate of potash or acetate of soda, to a solution of nitrate of silver, as long as a precipitate occurs, or by digesting the oxide or the carbonate of silver in hot and strong acetic acid; it is freely dissolved by a solution of cyanide of potassium. Cyanide of silver is generally prepared by adding a solution of cyanide of potassium to one of nitrate of silver as long as a precipitate occurs; the white precipitate, which is cyanide of silver, is insoluble in water, and is not perceptibly soluble in commercial hydrocyanic acid; it dissolves very freely in a solution of cyanide of ammonium, potassium, or sodium, and in hyposulphite of soda; it is also said to be soluble in solutions of ammonia, carbonate of ammonia, salammoniac, nitrate of ammonia, and ferro-cyanide of potassium.

131. M. Brandeley, a French experimentalist, makes the following remarks upon the preparation of cyanide of silver:—"To obtain a beautiful and easy deposit of silver, we choose, among all the salts of silver, the cyanide, as giving the best results; but as the dealers sell this at a high price, both amateurs and manufacturers reject it. Others, for the sake of economy in procuring it, purchase hydrocyanic acid; but this, also, is of too high a price; and independently of our being obliged to use it immediately, it is both dangerous and difficult to preserve, as the air and light decompose it. If we take commercial hydrocyanic acid which has been prepared fifteen days, and pour it into a solution of nitrate of silver, consisting of one part of the nitrate to six parts of water, cyanide of silver will be formed; but it is more or less yellow, and much ammonia and hydrocyanic gases are evolved. On the other hand, if we make a solution of cyanide of potassium, filter it, and dissolve cyanide of silver in it, this solution, which was clear and colourless, immediately becomes troubled and black, and betrays an odour of ammonia and hydrocyanic acid. The odour will continue as long as the solution exists, and a deposit of carbon will be found in the vessel containing it. This sediment arises from the decomposition of one part of the cyanide of potassium, caused by the presence of the cyanide of silver. Having occasion to use considerable quantities of the cyanide of silver, I dissolve pure silver in pure nitric acid; evaporate just to dryness; dissolve the nitrate of silver thus obtained in distilled water, and pass hydrocyanic gas (prussic acid) through it, from a mixture of pounded ferro-cyanide of potassium and sulphuric acid, diluted with twice its weight of water—continuing this as long as a precipitate will form. Wash the cyanide of silver, and preserve it below water, away from the light. Thus precipitated, the salt dissolves without residuum or colour, and gives splendid results."

With regard to this process, we may remark, that six parts of sulphuric acid should be mixed with from thirty to forty parts of water, and the mixture allowed to cool; then put it into a glass vessel (Fig. 86), together with ten parts of coarsely-powdered ferro-cyanide of potassium; heat must be applied until gas is evolved from the mixture, and continued as long as any is given off, or as long as a precipitate is produced in the silver solution, the gas being passed into the liquid by a suitable tube. (See Fig. 86). This process may yield a purer product than when the nitrate solution is precipitated by cyanide of potassium; but it cannot be very economical, because only half of the cyanogen of the ferro-cyanide passes over as hydrocyanic acid; the remainder is left behind, and is contained in the yellowish-white residuum in the gas-generating vessel.

Fig. 86.



132. *Silver Solutions.*—Silver has been deposited by the ordinary dipping or wash process, by the single cell, and by the battery process. The following are recipes for solutions, taken from various sources, adapted for silvering articles by the simple immersion or wash process, chiefly applicable to small articles, such as pins, buttons, buckles, coffin-nails, hooks-and-eyes, &c., where only a very thin coating of silver is required. The solutions in the proportions indicated, are used by adding a small quantity of water, sufficient to form the ingredients into a pasty liquid of the consistence of cream, stirring the articles thoroughly about in it, or rubbing them over with it until they have acquired the desired degree of whiteness:—1st, take equal parts of chloride of silver and bitartrate of potash; 2nd, take chloride of silver one part, alum two parts, common salt eight parts, and tartar eight parts; 3rd, take chloride of silver one part, prepared chalk one part, common salt one-and-a-quarter parts, and pearlash three parts; 4th, a "novargent" solution for resilvering old plated goods, consists of one

hundred parts of hyposulphite of soda and chloride, or any other salt of silver, fifteen parts. Compounds of this description are also used for silvering clock-faces, thermometer and barometer plates, and many other articles of copper and brass.

133. *Silvering by Immersing.*—Mr. Joseph Steele took out a patent, dated August 9th, 1850, for silvering articles, by immersing them in a silver solution in contact with a piece of zinc of proper size. The process is as follows:—Dissolve four ounces of pure silver in twenty ounces of nitric acid; also dissolve, separately, one-and-a-half pounds of common salt in one-and-a-half gallons of water; mix the two solutions together, allow the mixture to remain till clear, pour away the clear liquid, and wash the precipitate, which is chloride of silver; next fuse together twenty-four ounces of ferro-cyanide of potassium, and twelve ounces of carbonate of potash; and when the mass is cold, add it, together with the chloride of silver, to one gallon and a-half of water; boil the mixture, and filter it; it is then ready for use.

134. *Silvering Solution for Battery Process.*—Many solutions have been proposed and tried for depositing silver by the battery process, but none have stood the test of time and experience like the one composed of double cyanide of silver and potassium dissolved in water, and a little *free* cyanide of potassium added. It may be made of various strengths, from half an ounce of silver to the gallon of water, to two, four, six, or more ounces; and from an ounce of cyanide of potassium to several pounds per gallon, and still be effective in working. The formula of M. de Ruolz is as follows:—Dissolve one part of cyanide of silver and ten parts of cyanide of potassium in one hundred parts of water, and dilute the resulting liquid with water to the required strength.

135. *Silver Plating Solution.*—The following is the most practical method of making a large quantity of the ordinary cyanide of silver plating liquid:—Take four parts of grain silver, add it, in small portions at a time, to a warm mixture of about five parts by weight of strong commercial nitric acid (the acid varies greatly in strength), and one part of water, contained either in a glass or stoneware vessel. Gas will be evolved from the surfaces of the pieces of silver, and brown fumes of nitrous acid will arise from the mixture, which should be conveyed out of the apartment by means of the chimney. The action should be maintained moderate and uniform, and if it should become too strong, a little cold water should be added, and the mixture kept more cool; when the whole of the metal is dissolved, apply a greater heat, and evaporate the solution nearly to dryness, which will drive off any excess of acid that may be present; the resulting salt, nitrate of silver, may then be dissolved in a large quantity of water, in the proportion of half a gallon (more or less) to each ounce of the silver used; at the same time a solution should be made of from 3 to 3½ parts (according to its quality) of cyanide of potassium, in 30 or 40 parts of water, which is to be added gradually to the solution of nitrate of silver as long as it produces a precipitate; if too much be added, it will cause some of the precipitate to redissolve and be wasted; it will also make the liquid appear clear where it passes: in such a case the liquid should be stirred, then allowed to settle clear, and a small quantity of nitrate of silver, dissolved in *distilled* water, should be added as long as it produces a white cloud. By conducting the operation in a glass vessel, adding the liquid towards the latter period in small quantities at a time, and at intervals of a few minutes each, with gentle stirring immediately upon each addition, carefully observing when it ceases to produce a precipitate, the point of neutralisation may be very accurately determined. The liquid must now be allowed to remain undisturbed until quite clear, the clear portion poured steadily away from the precipitate of cyanide of silver, and the precipitate washed five or six times in a large quantity of water, by simply adding the water briskly to it, allowing it to settle, and then pouring off the clear portion. Next dissolve from 3 to 3½ parts (according to its quality) of cyanide of potassium in 20 parts of water, adding it, in portions at a time, to the wet cyanide of silver, with free stirring, until the whole is dissolved; then add about 3 parts more of cyanide of potassium to form *free* cyanide, and sufficient water to reduce the whole to the proportion of about one ounce of silver to the gallon: finally, when all the free cyanide is dissolved, filter the solution through a piece of unglazed calico. On the small scale, distilled water is used in the various parts of the process, except the washing; but, on the large scale, clean rain-water or spring-water is used in all the operations.

136. *Another Solution.*—The cyanide of silver plating solution may be made by other modifications of the chemical method than the one described: for instance, some electrotypists make the solutions by dissolving oxide, carbonate, or even chloride of silver in a solution of cyanide of potassium to saturation, and then adding an amount of free cyanide; by this process we are enabled to use caustic potash, carbonate of potash, hydrochloric acid, or common salt, instead of cyanide of potassium, for precipitating the nitrate of silver; nevertheless it still requires two equivalents of cyanide of potassium to be used as before—viz., one to convert the salt of silver into cyanide, and the other to dissolve the cyanide of silver formed; because, in all such cases, according to the researches of Messrs. Glassford and Napier,* when any salt of silver is added to a solution of cyanide of potassium, it is first converted into cyanide of silver at the expense of one portion of the cyanide of potassium; it then combines with the remaining cyanide to form double cyanide of silver and potassium, which dissolves in the water: therefore, by this modification of the chemical method, no cyanide of potassium is saved, and the carbonate of potash, hydrochloric acid, &c., are wasted. This modification has a still greater disadvantage; it introduces substances into the depositing liquid which are injurious. We have before said (90) that a good depositing solution should dissolve the anode freely, hold abundance of metal in solution, and not act chemically upon base metals, because it is such metals we generally wish to coat. Now, if instead of cyanide of silver, we add oxide of silver to the cyanide of potassium liquid, it converts part of the cyanide into caustic potash; if we add carbonate of silver, it converts it into carbonate of potash; and if chloride of silver, it converts it into chloride of potassium; and each of these substances, especially the last, diminishes the action of the liquid upon the dissolving plate, decreases its solvent power for cyanide of silver, makes its particles less mobile, and causes it to act in some degree upon base metals, and thus endangers the adhesion of the deposits upon them. Some electro-platers think the presence of these salts not injurious, but many consider them highly detrimental.

137. *Solution by Battery Process.*—The same silver solution may be formed by the battery process (89) as well as by the chemical method; and this process has its advantages and disadvantages: it is very convenient in making a small quantity of liquid, because it enables the operator to do so quickly, to avoid the trouble of making the nitrate solution, of precipitation, of washing, and of the attendant risk of loss of materials; but it has the disadvantage of converting a large proportion of the cyanide of potassium into caustic potash, by taking its cyanogen to form cyanide of silver, and setting the potassium free, which immediately combines with the oxygen of the water, forming caustic potash, which dissolves in the liquid. The hydrogen of the water is evolved at the cathode, and the dissolved potash gradually becomes converted into carbonate of potash by absorption of carbonic acid from the atmosphere. Neither caustic potash nor carbonate of potash are so injurious in the liquid as chloride of potassium; still they diminish the action of the liquid upon the dissolving plate, render it a worse conductor, reduce its solvent power for cyanide of silver, and make its particles less mobile.

138. *Solid Deposition of Silver.*—Mr. Alexander Parkes took out a patent, March 29th, 1841, for improvements in the solid deposition of silver. He converts an ounce of silver into oxide of silver, by first dissolving it in

---

* *Philosophical Magazine*, 1844.

nitric acid, and then precipitating it by caustic potash; he then dissolves the oxide, together with sixteen ounces of cyanide of potassium, in two gallons of water, and uses the resulting liquid for depositing solid articles in silver.

139. Mr. Edmund Tuck took out a patent, June 4th, 1842, for "improvements in depositing silver upon German silver." For plating the commoner qualities of this alloy, he uses a solution composed of sulphate of silver dissolved in a solution of carbonate of ammonia; and for the best quality, he uses cyanide of silver dissolved in a solution of carbonate of ammonia. The solutions are formed by dissolving 70 parts of carbonate of ammonia in distilled water, then adding 156 parts of sulphate of silver, or 134 parts of cyanide of silver, and boiling the liquid until the salt is dissolved: for coating common German silver, he adds half an ounce of sulphate of silver to 107 grains of bicarbonate of ammonia.

140. For depositing purposes, a solution composed of water 20 parts, cyanide of potassium four parts, and acetate of silver one part, conducts very freely, and yields a fine white deposit of silver. A solution composed of water 25 parts, prussic acid 65 parts, "black" cyanide of potassium 12 parts, and cyanide of silver 10 parts, is also a very good one.

141. Many electro-platers use a cyanide solution containing about half an ounce of silver to the gallon, and add a very large proportion of free cyanide to make it conduct freely: such a solution has the advantage of being comparatively inexpensive in its first formation, quick in working, and yields metal of an average character; but it is rather difficult to manage in hot weather, and dissolves the anode very rapidly, on account of the large proportion of free cyanide. In practice, the amount of silver to the gallon varies from half an ounce to about four ounces, but ordinary solutions contain about one or two ounces; the amount of *free* cyanide of potassium also varies from about half the weight of the silver dissolved in the liquid to five or ten times this quantity: a very good proportion is about three-fourths of the weight of the dissolved silver; but there is no rule generally recognised in the trade upon this point; some manufacturers use a very large and others a very small proportion.

142. A good plating liquid should contain one equivalent (65 parts) of pure cyanide of potassium, and one equivalent (134 parts) of cyanide of silver, besides *free* cyanide, and sufficient water to form a thin liquid. It is necessary to have *free* cyanide, because, in working the solution, insoluble cyanide of silver is formed, and requires *free* cyanide of potassium to combine with it and form the soluble double cyanide; at the same time, cyanogen and cyanide of potassium are set free at the cathode or receiving surface by the deposition of the silver; and as it requires some time for those substances to mix with the liquid and reach the dissolving plate, *free* cyanide must be provided. The necessity of having sufficient water to form a *thin* liquid, arises from the double cyanide formed at the dissolving plate, being specifically heavier than the liquid, having a tendency to sink to the bottom; whilst the cyanogen and cyanide of potassium set free at the surface of the articles, being specifically lighter, tend to rise to the surface. At the same time, each of them mixes more or less with the surrounding liquid by capillary attraction or adhesion; and the more dilute the liquid is, the more mobile are its particles, and the more rapidly does this mixture take place. This explains why strong silver solutions require more frequent stirring than weak ones to keep them uniform. In some manufactories, where they have steam-power at command, the articles are kept in constant motion by machinery swinging them gently to and fro; but in ordinary electro-plating establishments, the silver solutions are stirred every evening.

143. If a solution contain but little water and a large supply of free cyanide, and, from any cause, the battery current become suddenly weak towards the evening, the silver deposited upon the articles will be redissolved, in consequence of the liquid about the dissolving sheets having, by the day's work, become saturated with silver, and that about the articles become full of free cyanide; the two electrodes (*i.e.*, the dissolving plates and the articles) form a kind of voltaic battery (one metal in two liquids), which develops a current of electricity in an opposite direction to the original one, and thus redissolves the deposited silver.

144. *Bright Silver Solution.*—Much practical interest was for a long time attached to the anticipated discovery of a solution by which silver might be deposited in a *bright* condition, and the labour of burnishing be thereby avoided or lessened. This discovery was at last effected as follows:—Some operators at the electro-plate works of Messrs. Elkington and Mason, Birmingham, were engaged in experiments on moulds containing bisulphide of carbon: whilst these moulds were being coated with silver in the depositing vats, very peculiar appearances upon the various articles receiving a deposit in the vat were noticed, some having very bright patches upon them like burnished metal. From the known presence of bisulphide of carbon, experiments were tried of adding that substance to a quantity of silvering liquid, which ultimately resulted in success, and a patent was taken out by Messrs. Lyons and Millward, March 23rd, 1847; in which they give the following instructions for forming a "bright solution:"—"Add to the usual solution of silver in cyanide of potassium, bisulphide of carbon, terchloride or other chloride of carbon, sesquichloride of sulphur, or hyposulphite of either potash or soda. The bisulphide of carbon may be used alone or dissolved in sulphuric ether; or it may be used in conjunction with any of the other substances mentioned above; but the patentees prefer using it as follows: six ounces of bisulphide of carbon are put into a stoppered bottle, and one gallon of the usual plating liquid added to it; the mixture is then shaken and set aside for twenty-four hours; two ounces of the resulting solution are then added to every twenty gallons of the ordinary plating solution in the vat, and the whole stirred together: this proportion must be added every day, on account of the loss by evaporation; but when the mixture has been made several days, less than this proportion may be used at a time; when hydrocarbons are used instead of the bisulphide, a much larger quantity must be added. This proportion gives a bright deposit; but, by adding a larger proportion, a dead surface may be obtained, very different to the ordinary dead surface. This substance is generally employed throughout the trade, although few are licensed to use it. Other compounds are also used, but to a very limited extent: among these are sulphur and collodion. A solution of iodine and gutta-percha in chloroform is said to be more permanent in its effect than the bisulphide of carbon. The liquid is generally added to the vat in the evening, after the work has been taken out. A method of bright *gilding* has also been recently brought into use in the trade.

145. *Method of Making Cyanide of Potassium.*—As nearly all the solutions which are used for electro-silvering and gilding contain cyanide of potassium, and as this substance is used extensively in electro-deposition generally, it will be necessary for the practical plater to understand how it is made, and to possess information respecting its impurities, and the method of testing its quality. It is nearly always made by the following process:—Take ferro-cyanide of potassium (yellow prussiate of potash), pound it fine, and gently heat it in an iron pan, with constant stirring until quite dry; treat a quantity of the best quality of carbonate of potash in a similar manner. When they are perfectly dry, add about three parts of the carbonate to eight parts of the ferro-cyanide, and thoroughly mix them; heat the mixture rapidly in an iron ladle or crucible, until it melts into a clear liquid, when gas will be evolved from its surface. It should be maintained at a moderate or dull red heat about fifteen or twenty minutes, or until the end of a cold iron rod dipped into it shows a white sample. The fusion should not be continued until the evolution of gas ceases, or the product will be of a gray

colour. It should be kept covered as much as possible. By allowing it to stand undisturbed a few minutes towards the latter part of the operation, and occasionally tapping the sides of the ladle or crucible, the iron of the ferro-cyanide will settle at the bottom as a fine black powder; the colourless cyanide of potassium may then be poured off into a cold iron pan, or upon a thick and cold iron plate; it should be broken up whilst still warm, and preserved in a well-stopped jar.

The black sediment, which contains much cyanide of potassium, should be scraped out of the vessel while still hot, and preserved, as water will at any time dissolve the cyanide. If the process be well conducted, the product will be of a clear white colour, or, at most, but very slightly gray. A larger proportion of cyanide of potassium is obtained by this process than when ferro-cyanide alone is employed, because, in the former case, one-third of the cyanogen (that which was combined with the iron) combines with the potassium of the carbonate of potash, whilst in the latter case it is lost; the cyanide produced by the fusion of the ferro-cyanide of potassium alone is of a grayish-black colour, and is termed "black cyanide."

46. *Cyanide of Potassium.*—Commercial cyanide of potassium varies very much in price and quality. By dissolving several specimens of commercial black cyanide in water, and filtering the solution, we found the proportion of black impurity in them varied from one-fourth to one-sixth of their weight; and by experiments with the commercial white cyanide, we found that one part (200 grains) of it dissolved in about one-and-a-quarter parts (230 grains) of distilled water at 60° Fah., and that it dissolved much more freely in water containing hydrocyanic acid.

147. *Impurities in Cyanide of Potassium.*—According to the researches of Messrs. Glassford and Napier,[*] commercial white cyanide generally contains about thirty-five per cent. of impurities, and often as much as fifty per cent., in the form of carbonate and sulphate of potash, chloride of potassium, cyanate of potash, ferro-cyanide of potassium, and silica; and if the mixture of salts from which it is made be not dry, ammoniacal compounds will be also formed. The sulphate of potash and chloride of potassium occur in the commercial carbonate of potash; the silica is present when we operate with an earthen crucible: and even when the process is well conducted and pure materials used, the product contains twenty per cent. of cyanate of potash, produced partly by the contact of the air with the melted mixture.

148. *Testing Cyanide of Potassium.*—According to the same experimentalists, the quantity of pure cyanide in any given sample of cyanide of potassium may be correctly ascertained thus:—Make two solutions, one of the given cyanide and one of nitrate of silver, each containing known weights of the salts—say one ounce of the cyanide dissolved in six ounces of distilled water in a graduated glass vessel, and 175 grains of the crystallised nitrate dissolved in about two or three ounces of distilled water; add the cyanide solution carefully and slowly to the nitrate of silver liquid, until the precipitate first formed is all redissolved. The quantity of the cyanide solution required to effect this (with the above quantity of nitrate of silver) will have contained 130 grains of pure cyanide; and, from the quantity used, we may easily calculate the amount of pure cyanide in the whole ounce. It is said, that "when nitrate of silver is added to a solution of cyanide of potassium, so long as the precipitate formed is all redissolved, we obtain the *whole* of the cyanide of potassium in combination with the silver: none of the other salts in solution take any part in the action, even though they be present in a large proportion. This enables us to test the exact quantity of cyanide of potassium in any sample."

149. *Chemical Characters of Cyanide of Silver.*—In the presence of cyanide of potassium, as we are informed by Messrs. Glassford and Napier, cyanogen has a greater affinity for silver than anything else has—decomposing every salt of silver except the sulphide, and forming cyanide of silver. In dissolving the oxide, carbonate, chloride, or ferro-cyanide of silver, in a solution of cyanide of potassium, they are all decomposed, and cyanide of silver always formed. Cyanide of silver should be dried below 260° Fah.: hydrochloric acid decomposes it with a solution of hydrocyanic acid gas; cold nitric acid has no action upon it; a boiling mixture of sulphuric acid and water decomposes it, with escape of hydrocyanic acid gas, and formation of sulphate of silver; it is soluble in the alkaline chlorides, but its best solvent is an aqueous solution of cyanide of potassium, of each of which one equivalent is required. The resulting solution, when evaporated, yields crystals of double cyanide of silver and potassium, which are soluble in eight parts of cold and in one part of boiling-water. The solution of this double salt, which is nearly the same as the ordinary plating solution, may be boiled for any length of time without being decomposed, and it is very little affected by light; it is decomposed by all acids, and they precipitate the silver as cyanide of silver: the hydro-acids—hydrochloric acid, for example—decompose the cyanide of silver also; sulphuretted hydrogen precipitates the silver as sulphide of silver.

150. *Gold Solution.*—Various salts of gold have been used for electro-deposition; among which are the hyposulphite, sulphite, iodide, bromide, terchloride, cyanide, and sulpho-cyanide. Finely-divided gold, which is sometimes used for dissolving, may be obtained by adding a solution of protosulphate of iron to a solution of terchloride of gold, as long as a greenish-brown precipitate occurs; this is gold in a state of very minute division. Oxide of gold is obtained by adding to a solution of terchloride of gold a cold solution of caustic potash, until it ceases to produce a precipitate; or by digesting terchloride of gold with magnesia, washing the fresh precipitate, first with dilute nitric acid, and then with water only. Iodide of gold is formed, either by digesting oxide of gold in hydriodic acid, or by adding a solution of iodide of potassium to a solution of terchloride of gold as long as a precipitate is produced—washing the precipitate with water; it is of a yellow colour, insoluble in cold water, but freely soluble in a solution of iodide of potassium. Bromide of gold may be formed either by digesting finely-divided gold, or oxide of gold, in liquid bromine contained in a stoppered bottle. It is a salt of a rich red colour, and is soluble in water.

151. *Chloride of Gold.*—Terchloride of gold, commonly known as chloride of gold, is the most usual salt of the metal, and its preparation requires separate explanation. It is formed as follows:—Take a mixture of two or three measures of hydrochloric acid, and one measure of nitric acid; make the mixture hot, and add pure grain gold to it as long as it will dissolve: it evolves gas whilst dissolving. When it is all dissolved, slowly evaporate the liquid until it crystallises to a dark ruby-red mass; or it may be of a yellow colour, according to the proportions of the ingredients. This is terchloride of gold, and contains one equivalent (197 parts) of gold, and three equivalents (106·5 parts) of chlorine; if it be too much evaporated, chlorine gas will be evolved, the gold will be set free and be mixed with the salt, and will precipitate on dissolving the salt in water. To produce the *yellow* chloride, mix together, in a glass or stoneware vessel, one part, by weight, of nitric acid, three parts of hydrochloric acid, one part of fine gold, and one part of water: cover the vessel with a glass dish, make the liquid quite hot, and maintain the heat until the red vapours cease; if some of the gold remain undissolved, add more of the liquid mixture, and treat as before: when the vapours cease, remove the glass cover, and replace it by folds of blotting-paper, and evaporate until it crystallises, on *cooling*, into yellow chloride of gold. The red chloride is formed in the same manner, except that the liquid mixture should be composed of one part of nitric, and two parts of hydrochloric acid, more being added than is necessary to dissolve all the gold. One ounce of gold will dissolve in

---

[*] *Philosophical Magazine*, 1844.

about four ounces of the mixture, and when crystallised into the red mass, will weigh about one ounce and 165 grains.

152. *Cyanide of Gold.*—"Cyanide of gold is formed by cautiously adding a solution of cyanide of potassium in six parts of water, to a normal solution (*i.e.*, not containing any *free* acids) of terchloride of gold, consisting of one part of the chloride and five parts of water, until a copious yellow precipitate settles down; if more cyanide of potassium be added, the precipitate becomes dirty yellow, and is more quickly deposited; a still larger quantity renders it orange yellow. It is a crystalline powder, permanent in the air. By ignition it is resolved into gold and cyanogen gas; it is not decomposed by sulphuric, hydrochloric, or nitric acids, nor by aqua regia, unless freshly precipitated, and then only slowly. It is not decomposed by sulphuretted hydrogen; hydrosulphate of ammonia dissolves it slowly but completely, forming a colourless solution, from which, by the addition of acids, sulphide of gold is precipitated. It dissolves in aqueous solutions of ammonia, hyposulphite of soda, or alkaline cyanides; but not in water, alcohol, or ether."

153. "Gold precipitated from a solution of chloride of gold by protosulphate of iron, dissolves in a boiling solution of cyanide of potassium; a hot solution of cyanide of potassium will also dissolve ordinary metallic gold if air be present. Both oxide of gold and aurate of ammonia, dissolve completely in a solution of cyanide of potassium, and form double cyanide of gold and potassium. Cyanide of gold requires 23 parts of a solution of cyanide of potassium in water to dissolve it. For every one part of gold to be dissolved by the battery process, a solution of six parts of cyanide of potassium, in from two to four times their quantity of water, at 100° Fah., is required; two electrodes of gold, connected with a suitable battery, are to be immersed in it until the required quantity of gold is dissolved."—"The crystallised cyanide of gold and potassium dissolves in seven parts of cold, and in half a part of hot water;[*] in four parts of cold and in 0·8 parts of hot water.[†] It dissolves very sparingly in alcohol. Its aqueous solution gilds copper and silver by simple immersion, especially if hot, and those metals are dissolved."

154. *Gilding by Immersion.*—The following solutions have been used for gilding by the simple immersion, or "water-gilding" process:—First, dissolve five troy ounces of grain gold in fifty-two avoirdupois ounces of hot aqua regia, until vapours cease to be evolved. Decant the clear liquid when cool; dilute it with four gallons of distilled water; add twenty pounds of purified bicarbonate of potash, and boil it for two hours. The articles to be gilt are immersed in the liquid from a few seconds to one minute, according to the kind of metal immersed, and the temperature and newness of the liquid; warmth assisting the action, and a new liquid acting more quickly than an old one. Second: for gilding silver articles, dissolve equal parts of bichloride of mercury (corrosive sublimate) and sal-ammoniac in nitric acid; add pure gold to it, and evaporate the liquid by heat to half its volume. Apply the liquid, while hot, to the surface of the article.

155. Joseph Steele's patent, dated August 9th, 1855.—Dissolve an ounce of gold in a mixture of four ounces of hydrochloric acid and eight ounces of nitric acid, and evaporate the solution to dryness. Fuse together 24 ounces of ferro-cyanide of potassium, and 12 ounces of carbonate of potash: when this is nearly cold, dissolve in two or three gallons of pure boiling-water; cool and filter the solution; then add the chloride of gold, and boil for a quarter of an hour. The articles to be coated are connected with a piece of zinc, of suitable size, and immersed in the liquid, the latter being at a temperature of 80° or 85° Fah.

156. *Gold Solution for the Battery Process.*—For the battery process there are many gold solutions, though but few good ones:—1st. The hyposulphite of gold and soda—formed by dissolving chloride of gold in a solution of hyposulphite of soda; which is not considered a good liquid for practical purposes. 2nd. The sulphite of gold and potash, used by Mr. Woolrich: his solution is made by adding sulphite of potash to water, saturating five-sixths of the resulting liquid with oxide of gold, and then adding the other portion of solution to form *free* sulphite. 3rd. The terchloride of gold dissolved in water is a very inferior liquid for practical purposes, because all the common metals decompose it. 4th. The bromide of gold, proposed by Mr. Spencer, is made as follows:—"Make a mixture of equal parts of bromine and alcohol; and of this mixture take one part, of acetic acid one part, and four parts of water containing a few drops of sulphuric acid." The resulting liquid is then nearly saturated with gold by suspending in it two electrodes of that metal, and connecting them a sufficient time with a suitable battery; when nearly saturated, add to the solution three times its volume of water containing a few drops of sulphuric acid.

157. *Electro-Gilding Liquid.*—The best liquid that has yet been tried for practical electro-gilding, consists of the double cyanide of gold and potassium dissolved in water. It was first patented by Messrs. Elkington, and may be formed, either by dissolving finely-divided gold, or any salt of gold, in a solution of cyanide of potassium; or by the battery process, by suspending two electrodes of gold in a solution of cyanide of potassium, and passing a current from a small battery until the cathode receives a proper deposit, the liquid being at about 100° or 150° Fah.

158. *Cyanide of Gold by Chemical Process.*—The cyanide of gold and potassium gilding solution is often made by the chemical method as follows:—Form some terchloride of gold (151), and dissolve it in water; then either add a cold solution of caustic potash as long as a precipitate is produced, filtering and washing the precipitate with distilled water, or by digesting the chloride solution with magnesia. Filter, and wash the precipitate first with nitric acid, and then with distilled water; or add to the chloride liquid a solution of carbonate of ammonia, until a precipitate ceases to be formed; filter, and wash the precipitate with water The precipitates produced by potash or by magnesia, consist of oxide of gold; whilst those produced by ammonia, or its carbonate, are aurate of ammonia (fulminate of gold), which is a very explosive compound. The precipitate, after being well washed by the successive additions of clean water, should be added, whilst still wet, to a solution of cyanide of potassium, containing the proportion of one pound of cyanide to one gallon of water; and then about one-fifth more of the same solution should be added to form *free* cyanide. A very good proportion of the ingredients is, one ounce of gold, one pound of cyanide of potassium, and one gallon of water. The wash-waters should not be thrown away without being tested for gold, by immersing a piece of bright zinc in them, and observing if it receive a yellow deposit; in that case, a solution of protosulphate of iron should be added as long as a precipitate of a greenish-brown powder, which is metallic gold, is produced. If this fail to precipitate the whole of the gold, a sheet of bright zinc should be immersed in the liquid, taken out occasionally, and the deposit of gold brushed off by a hard brush in water containing a little sulphuric acid. The greater the quantity of *free* acid contained in the original chloride solution, and the larger the excess of potash, ammonia, or carbonate of ammonia added, the greater is the amount of gold dissolved in the wash-waters. If, when we dissolve the terchloride of gold in water, a yellow powder remain undissolved at the bottom of the vessel, it indicates that there is no free acid in the salt; and it may be redissolved by the addition of a small quantity of the mixture of nitric and hydrochloric acids, and the application of heat.

159. *Solution by Battery Process.*—The same solution may be made by the battery process, thus:—Dissolve some cyanide of potassium in hot distilled water, in the proportion of from one to two pounds to the gallon; nearly fill a small porous cell with the liquid, and immerse it nearly to its edge in the solution; place a large gold anode in the outer liquid, and a small bright copper cathode in the liquid of the porous cell, and

---

[*] Himly.

[†] Glassford and Napier.

connect them with about three pairs of Smee's batteries—the gold anode with the platinised silver by one wire, and the copper cathode with the zinc by another wire, allowing the current to pass, until, by transferring the cathode for a short time to the outer liquid, it receives a good deposit of gold, the solution being maintained at a temperature of about 150° Fah.; the liquid of the porous cell should then be transferred to the outer solution, and the process stopped. The amount of gold dissolved is not of material consequence provided the deposit be good, as a solution may contain from half an ounce to four ounces to the gallon, and be a good depositing liquid.

160. *Gilding Solution of M. Ruolz.*—"Dissolve ten parts of cyanide of potassium in 100 parts of distilled water; filter it, and add one part of cyanide of gold, prepared with care, well washed, and dried out of the influence of light; keep the mixture in a closed glass vessel, at the temperature of 60° to 77° Fah., for two or three days, out of the presence of light, and frequently stir it."

161. *M. Becquerel's Gilding Liquid.*—"Dissolve one part of terchloride of gold and ten parts of ferro-cyanide of potassium in 100 parts of water; filter the liquid, to remove the separated cyanide of iron; add 100 parts of a saturated solution of ferro-cyanide of potassium, and dilute the mixture with one or two volumes of water. In general, the tone of the gilding varies according as the solution is more or less dilute; the colour is most beautiful when the liquid is most dilute, and most free from iron. To make the surface bright, it is sufficient to wash the article in water, acidulated with sulphuric acid, rubbing it gently with a piece of linen cloth."

162. *Gilding Liquids of M. Fizeau.*—"1st. Dissolve one part of dry chloride of gold in 160 parts of distilled water; then add, little by little, a solution of carbonate of potash in distilled water until the liquid begins to become cloudy; we may use this liquid immediately." And, 2nd, used by M. Lerebour:—"Dissolve one gramme[*] of chloride of gold, and four grammes of hyposulphate of soda, in one litre of distilled water."

163. *M. Levol's Solution for Gilding Silver.*—"Dissolve neutral chloride of gold, then add an aqueous solution of sulpho-cyanide of potassium, until the precipitate first formed is redissolved. The liquid will retain a slightly acid reaction; if it lose this, it must be renewed by adding a few drops of hydrochloric acid."

164. *By M. de Briant.*—"Dissolve thirty-four grammes of gold in aqua regia, and evaporate the solution until it becomes neutral chloride of gold; then dissolve the chloride in four kilogrammes of warm water; and add to it 200 grammes of commercial magnesia, carefully sifted. The gold is precipitated in union with the magnesia; filter and wash with pure water; digest the precipitate in forty parts of water mixed with three parts of nitric acid to remove the magnesia; then wash the oxide of gold remaining with water, until the wash-water exhibits no acid reaction. Next dissolve 400 grammes of ferro-cyanide of potassium, and 100 grammes of caustic potash, in four litres of water; add the oxide of gold, and boil the solution about twenty minutes. When the gold is dissolved there remains a small amount of iron precipitated, which may be removed by filtration, and the liquid, of a fine gold-yellow colour, is ready for use. It may be used either hot or cold."

165. *Formulas of M. J. L.*—"1st. Take thirty-one grammes and twenty-five centigrammes of oxide of gold, five hectogrammes of cyanide of potassium, and four litres of water, and boil them together half-an-hour. The resulting solution must be worked hot, and may be used to gild copper, brass, and silver. 2nd. Dissolve ten parts of ferro-cyanide of potassium and one part of dry terchloride of gold in 100 parts of water; oxide of iron will be precipitated. Boil the solution two or three hours, in a porcelain or glass vessel, until a precipitate collects at the bottom and the supernatant liquid is transparent and of a canary-yellow colour; filter the solution, and dilute it with three times its volume of water."

166. A process or branch of trade, termed "solid depositing," has of late years been gradually extending itself. It consists in making solid articles of gold and silver, by electro-deposition, upon gutta-percha or other moulds—such, for instance, as watch and clock faces, ornamental snuff-boxes, and other articles elaborately chased or engraved, or which have very complex or under-cut ornaments upon them; the expense of multiplying these by the electro-process being less than by the ordinary means. Mr. Alexander Parkes took out a patent, dated March, 1841, for a solution for depositing solid articles in gold. It is formed thus:—Dissolve one ounce of pure gold in aqua regia, and evaporate the solution to dryness; then add two gallons of water and sixteen ounces of cyanide of potassium, and work the resulting liquid at a temperature of about 120° or 130° Fah.

167. *Salts of Platina.*—The only common salt of platina is the bichloride: it is formed by adding pieces of platina foil to hot aqua regia as long as gas is evolved from them; the solution, which is then of a deep-red colour, should be evaporated nearly to dryness, and left to cool.

168. *Platina Solutions.*—For platinising silver by simple immersion process, we may use a solution consisting of bichloride of platina, dissolved in water containing one-fourth its volume of nitric acid, or we may use simply a very hot aqueous solution of the bichloride alone. Nearly all metals decompose the bichloride solution, and become coated with platina in it by simple immersion. For the battery process we may use solutions of the iodide, bromide, or bichloride, or the double chloride of platina and sodium. The solution of the double chloride of platina and sodium is made by dissolving one equivalent (169·7 parts) of bichloride of platina and one equivalent (58·5 parts) of common salt, in water; it requires a small anode of platina and a very weak battery to obtain a reguline deposit. A good solution for depositing reguline platina may also be made by dissolving bichloride of platina and common salt in a solution of caustic potash.

169. *Palladium Solutions.*—A solution of double cyanide of palladium and potassium may be used for depositing palladium. It may be made by chemical means, by dissolving palladium in nitric acid, precipitating the solution by a solution of cyanide of potassium, washing the precipitate, and dissolving it in a solution of cyanide of potassium to saturation, and then adding a little free cyanide; or it may be easily made by the battery process, by passing a current through a large palladium anode in a solution of cyanide of potassium, until a clean smooth cathode receives a good deposit. This is an excellent solution for depositing reguline metal; it acts upon the anode with uncommon energy, conducts freely, and deposits plenty of reguline metal: a thin deposit of palladium obtained in this solution has been used for fixing Daguerreotype pictures, instead of gold, and is said to give them a finer tone.

170. *Selecting Practical Liquids.*—Having enumerated nearly all the solutions which have been used for depositing different metals, and described the modes of forming them, we now offer a selection of those which are in most general use in the trade.

1st. For depositing zinc, which is not very often attempted, the sulphate solution (105) may be used.

2nd. For depositing copper upon all ordinary metals (except zinc, tin, lead, iron, and steel), and upon gutta-percha, wax, and elastic moulds, after being made

---

[*] The following table of some French weights, &c., may be of use to the student. We may observe, that French weights and measures have an invariable relation to the *metre*, which is equal to about 39 inches British. A gramme, which is the unit of French weights, is equal to about 15½ grains British, and represents the weight of a cube of water at 40° Fah., the sides of which measure the 1-100th of a metre each.

FRENCH.	BRITISH.
The Gramme	15½ grains nearly.
,, Kilogramme (1,000 grammes)	2⅕ lbs. ,,
,, Litre (1 kilogramme)	2⅕ ,, ,,

This being the unit of French liquid measure, equals the weight of a cube of water, each of the sides of which measures the tenth part of a metre.

The Centigramme is the one-hundredth part of a gramme.
The Hectogramme is equal to one hundred grammes.

conductible by the battery process, the sulphate solution (120) is in general use; but for surfaces of tin, lead, iron, or steel, the solution of cyanide of copper and cyanide of potassium (120) is used.

3rd. For the deposition of brass upon all ordinary metals, the patented solution of Messrs. Morriss and Johnson (127) is very successfully used; the solutions of Brunel (126) and Salzede (125) are also in practical use; and, in the United States of America, a solution very similar to that of Messrs. Morriss and Co. is employed.

4th. For depositing silver upon all common metals, the solution of double cyanide of silver and potassium (135) is almost universally used; the only exception is where the double sulphite of silver and potash is used, but only to a small extent, the magneto-machine being in some cases employed.

5th. For gilding all ordinary metals, almost the only liquid used is the double cyanide of gold and potassium (157 and 158); the only exceptions being a few minor modifications for operations on the small scale.

6th. For platinising, the only solution in practical use is the bichloride (167).

7th. For *solid* deposition of silver and gold, the patented solutions of Mr. Alexander Parkes (138 and 166) may be employed.

171. *Preparing Metal for Receiving a Deposit.*—The electrotypist having acquired a general knowledge of depositing liquids, as well as of the necessary manipulation, and having made the several solutions necessary for his ordinary use, will require to prepare his articles for receiving a deposit. All metallic articles must be cleaned, and otherwise prepared, before they are fit to receive a deposit; this preparation differs, of course, according to the nature of the article, whether the deposit be required to adhere firmly to the surface, or merely to be used as a matrix, from which the deposited metal is to be removed.

172. *Cast Iron and Zinc.*—Articles formed of zinc, wrought-iron, cast-iron, or steel, are first immersed for a few minutes in a boiling solution of caustic potash, to remove any grease, tar, or oily substance which may be upon them; they are then washed in water; and those of wrought or cast-iron are immersed in "pickling liquid" (82), until the acid acts rather freely upon them; rough cast-iron requires a stronger liquid than smooth wrought-iron: after being again washed in water, they are "scratched" at the brush (80). If they are very coarse castings or rusty articles, they may require several soakings in the dilute acid, and scourings with sand and a harsh brush, and even filing, to make them quite clean.

173. *Copper, Brass, and German Silver.*—Those formed of copper, brass, or German silver, should be boiled in the potash liquid, washed in water, and dipped into nitric acid, or into the "dipping liquid" (82). They are then to be washed in water, and dipped into a solution of nitrate or cyanide of mercury (84), before immersing them in the silvering solution.

174. Sometimes, in order to assist in cleaning the articles, they are suspended for a short time in the depositing liquid, in contact with the negative pole of the battery; this dissolves the surface, and loosens their impurities, unless they are very foul, or the solution is too valuable. In every case they should be well rinsed with water to remove the adhering acid, before dipping them into the mercury solution, or immersing them in the depositing vat. All objects which are to have a definite weight of metal deposited upon them, are weighed, and their weight noted down after they have been cleaned.

175. *Wiring Articles.*—The articles having been cleaned thoroughly, have wires of copper attached to them, to suspend them in the vat. The wires differ in size with different articles; with small ones, such as spoons, knives, forks, snuffers, teapots, jugs, and such articles, size No. 20 or 22 of the Birmingham brass wire gauge, and about eighteen or twenty inches long, are used. Very large articles, such as fire-irons, fenders, hat-stands, and articles of ornamental iron-work, are suspended in the solution by strong copper or brass hooks; in some cases where a powerful and certain connection is required, the wires are soldered to the articles.

176. *Preparing Articles for Adhesive Deposits.*—We have already explained how necessary it is that all articles intended for the depositing vat should be cleaned in the most perfect manner possible, before being immersed in the depositing liquid, otherwise the deposit will not adhere. Articles of copper, brass, or German silver, which are to be silver-plated, should also be dipped into one of the solutions of mercury (84); otherwise the deposit will not adhere at all, or will vary in appearance in different parts; and in consequence of this perfect degree of cleanliness required, the cleaning of them often involves more trouble than the depositing. All articles should be plunged, while still wet from the cleaning process, into the depositing vat. The practical minutiæ of preparing the surfaces of different metals for receiving adhesive deposits of other metals, vary in almost every manufactory, and much information yet remains to be developed upon this point For want of this knowledge, the most skilful operators sometimes fail in producing perfect adhesion, especially upon zinc, cast-iron, steel, and Britannia metal.

177. *Preparing Metals for Non-adhesive Deposits.*—Metal articles which are to receive non-adhesive deposits, such as medallions, of which copies are desired in copper, should be allowed to remain a sufficient time to slightly oxidate after being cleaned, before being plunged in the depositing vat, the oxide preventing adhesion. In some cases they are rubbed over with cotton wool slightly moistened with a very weak solution of bees-wax dissolved in camphine, in the proportion of a piece of wax of the size of a small pea, in a quarter of a pint of the spirit; others use a little sweet oil, which is immediately wiped off with a fresh piece of dry cotton wool.

178. *"Stopping off" to Prevent Deposition.*—Many articles which are to receive deposits require to have portions of their surface "stopped off," to prevent the deposit spreading over those parts: for instance, in taking a copy of one side of a metal medallion, the opposite side must be coated with some kind of varnish, wax, or fat, to prevent deposition; or in gilding the inside of a cream jug which has been silvered on the outside, varnish must be applied all round the edge on the outside for the same reason. For gilding and other hot solutions, copal varnish is generally used; but for cold liquids and common work, an ordinary varnish, such as engravers use for a similar purpose, will do very well. In the absence of other substances, a coating of sealing-wax dissolved in naphtha will answer every purpose.

179. *Moulding and Copying Works of Art.*—The electrotypist who includes in his business the multiplication of works of art, as well as the simple plating of metal articles, will require a knowledge of the art of moulding. To copy both sides of a metallic coin or medal in the mixture of gutta-percha and marine glue recommended (85), take a strip of thin sheet copper, brass, or tinned iron, about an inch wide; wind it closely round the edge of the medal, and solder its ends together; wipe the medal and take two balls of the composition, quite hot and soft, and press them simultaneously against the two faces of the medal, working the material from the centre towards the circumference to exclude bubbles of air; place two thick plates of cold metal, one on each side, and gradually screw up the whole in a vice, or screw-press, gently at first, but increasing the pressure to a high degree as the materials become hard. When it is quite cold, which will be in about two hours, the two copies may be easily removed from the original, by inserting the end of a gimlet in their backs, and drawing them out; they are easily removed, because the composition slightly contracts in cooling. They will present fine impressions of the original, and be perfectly free from air-bubbles, when the operation has been carefully performed.

180. *Elastic Moulding.*—If the medallion be under-cut, it must be copied in "elastic moulding" (86), thus :—

Encircle its edge by a strip of stout paper, and pour the mixture upon its surface quite hot, and of the consistency of treacle, to the depth of half an inch or more, according to the size of the medal and the depth of its hollow parts, brushing its surface beneath the liquid with a brush having fine and long hairs, to remove air-bubbles. Allow the mixture to remain until it is quite firm, which will be from two to twenty-four hours, according to its bulk; take off the paper, and remove the mould very gently, carefully stretching and drawing it at the same time in the direction of the overhanging parts, to prevent injury. Should the object to be copied be a hollow metallic bust, proceed as follows:—Partly fill it with sand, to make it heavy and thus prevent its rising in the liquid, and cover its opening by sticking a piece of millboard strongly over it; then place the bust in the centre of a cylindrical and tapering vessel, a few inches deeper and wider than itself, and pour the melted composition in steadily, until it is a few inches above the top of the head, tapping the bust, and inclining the outer vessel, to facilitate the escape of air-bubbles. When the composition is quite firm, which it will be in about twenty hours, it may easily be removed from the vessel by shaking, the vessel having been previously well oiled; the mould may then be removed from the bust by previously marking on its lower end the position of the face, passing a knife carefully up the back of the bust nearly to the crown of the head, and opening the elastic mould with the hands, whilst a second person lifts out the bust. If the original bust be composed of plaster, it must be previously saturated with oil, to prevent the melted composition adhering to it.

181. *Rendering Moulds Conductible.*—To render the surfaces of non-metallic moulds conductible, there are two methods in use: first, to cover them with a thin film of blacklead by brushing; and, second, to coat them with a minute film of gold or silver by chemical means. The first of these methods is generally used for moulds composed of gutta-percha, wax, resinous composition, or plaster saturated with oil, where the parts are not much under-cut; and the second for elastic moulds, because the blacklead cannot be readily applied to all their recesses.

182. *Blackleading.*—To apply blacklead to a small round or oval medallion formed of gutta-percha and marine glue, first insert the sharp end of a piece of copper wire, size No. 16 or 18, and about fifteen or twenty inches long, into the edge of the mould near its face; then pass a piece of fine copper wire, size No. 28 or 30, once tightly round the edge of the mould, close to its face, securing its ends to the other wire. Fix a strip of paper about one inch wide, by means of sealing-wax, tightly round the edge, to prevent the blacklead passing anywhere except upon the face of the mould. Apply the blacklead by a soft camel's-hair brush with a large and thick body of short hairs, breathing upon the face of the mould occasionally to facilitate the adhesion of the material. When the medal is perfectly black and bright, blow off the superfluous blacklead, and remove the paper; it is then ready for receiving a deposit, the whole operation occupying about ten or fifteen minutes with a small object the first time of preparing it, but less in subsequent operations. If the mould be very large, and especially if it have deep hollows in its surface, it will require, after being blackleaded, to have several short and fine copper "guiding-wires" carefully attached to the main wire, and their free ends slightly inserted in the face of the mould, in the most hollow and distant parts, or to lie in contact with them, in order to cause the deposit to commence and spread there as well as round the edge. If this precaution be not taken, the deposit will be much thinner over those parts than upon the nearer and more prominent places, and sometimes will not spread over them at all.

183 *Preparing the Surfaces of Elastic Moulds.*—Elastic moulds are treated in a different manner. First, a stout connecting wire is attached; then a number of fine copper "guiding-wires" are twisted round it, and their free ends slightly inserted in the face of the mould, in all the hollow and distant parts; the mould is then either dipped into the phosphorus solution (87), or its surface is covered with that liquid; and, after it has been drained clean, it is allowed to remain until perfectly dry; the silver solution is next applied to it (87), in like manner, for several minutes, until it appears black, with a metallic lustre like black china; it is then gently rinsed with distilled water, and the gold solution applied in the same way (87), which gives it a yellowish aspect; after another rinsing in distilled water, it is ready for receiving a deposit.

184. *Moulding by Phosphorus Composition.*—Some objects which are not much under-cut, are moulded in the phosphorus moulding composition (87); and, in some cases, where they are under-cut, as well as busts, they are first copied in the elastic moulding, and then the elastic mould is copied in this material, the composition being but barely melted that it may not dissolve the elastic moulding. In either of these cases, instead of immersing the mould in the phosphorus, silver, and gold solutions, it is only immersed in the two latter, in the manner already described, the phosphorus contained in the mould itself serving to reduce the silver and gold.

185. *Preparing Surfaces of Glass for Deposition.*—Glass surfaces may be prepared for receiving a deposit by means of the phosphorus, silver, and gold solutions, but not very satisfactorily. A better method, which we have tried, has been silvering them by Drayton's patent process, thus:—Take one part, by weight, of liquid ammonia, three parts of alcohol, two parts of nitrate of silver, and three parts of distilled water; dissolve the silver salt in the water, add the liquid ammonia and the alcohol, shake the mixture, allow it to remain until quite clear, and pour off the clear part into the glass vessel to be silvered, which must be perfectly clean: then add to it one quarter of a part of grape-sugar dissolved in weak spirits of wine, mix the liquid, and heat it to about 150° or 160° Fah. for about twenty or thirty minutes, and the glass vessel will become silvered. The liquid may then be removed; the vessel gently rinsed with distilled water; a connection is to be formed by means of a fine copper wire with the film of silver and the battery; the vessel filled with a suitable depositing liquid, an anode immersed, and the surface deposited upon in the ordinary way. If the process be successfully performed, the deposit, whether of silver or copper, will spread instantaneously over the silvered surface. The only way by which we have been able to form an adhesive deposit upon glass or porcelain, has been to send the articles to a glass and porcelain gilder, and have gold-leaf burnt into their surfaces, and then depositing upon them in the usual manner may be successfully effected.

186. *Immersion of Articles in the Vat.*—The operator having prepared the various articles and moulds, will immerse them in the depositing solution, having previously introduced the anode and completed all the connections, taking care always to connect the article to receive the deposit with the zinc of the battery, and the metal to be dissolved with the copper or silver plate.

187. *Regulation of Battery Power.*—In depositing all metals, it is of the greatest importance that the battery power be properly regulated; and this may be done in a variety of ways, which collectively consist either in making alterations in the battery, in the depositing vessel, or in the wires connecting them. The *intensity* of the current is increased by increasing the number of alternations of the battery plates. Resistance to the current is diminished by increasing the conductibility of the battery liquid or depositing solution, which may be effected either by the addition of free acid to the battery or more salt to the solution; or by increasing the thickness and decreasing the length of the connecting wires. The *quantity* of the current is increased by immersing all the battery plates deeper in their liquids; also by some of those means which increase the intensity. Both the intensity and the quantity may be decreased by separating the electrodes in the depositing vessel farther asunder, or by interposing a long and fine iron wire in

the circuit. The most usual means adopted of increasing the *intensity* of the current, is to add to the number of the batteries; and for increasing the *quantity*, to immerse all the battery plates deeper in their liquids.* Sometimes, to increase the power, the temperature of the liquid may be raised, or the article placed nearer the dissolving metal; and when a smaller quantity of current is required than the ordinary batteries can conveniently supply, a piece of sheet metal may be hung in the depositing solution with the receiving article, to receive a portion of the deposit, and thus transfer some of the power from the article to itself

188. *Intensity and Quantity of the Current.*—The intensity of the current obtained from a series of batteries, depends upon the *number of alternations* of the metals; whilst its *quantity* depends upon the *amount of immersed surface in each alternation*; and it makes no difference whether that amount of surface is in one battery plate or in many, or in one or many containing vessels. A series of similar batteries may be so connected together by wires or other conductors, as to give either an intensity or a quantity of current, provided they have screws or other conveniences for attaching the wires to the plates. For instance—1st, if we have four pairs of plates, in four separate cells, and connect them alternately, thus (Fig. 87), zinc, silver—zinc, silver—zinc, silver—zinc, silver, with wires from the terminal plates, we obtain a current possessing the intensity of four pairs, and the quantity of one; but if, 2nd, they are connected, all the zincs by one wire, and all the silvers by another wire (Fig. 88), with one portion of each wire left convenient for making connections, we obtain a current possessing the quantity of four pairs, and the intensity of one; and, 3rd, if they are arranged in two series or rows, two pairs in each, each series being connected intensity-fashion, the end silvers of each row facing one way and connected by one wire, and the terminal zincs facing the opposite way and connected by another wire, and these wires left free for connection with the vat (Fig. 89), we obtain a current possessing the intensity of two pairs and the quantity of two. By contrivances of connection like these, any number of batteries, provided they are similar in kind, charged alike, and have suitable connecting screws attached, may be connected together so as to give any desired quantity or intensity of current within the limits of their power: thus, a battery of one hundred pairs may be arranged to yield a current having the intensity of one hundred pairs, and the quantity of one; the quantity of one hundred, and the intensity of one; the intensity of fifty, and the quantity of fifty; or any intermediate degree of each.

Fig. 87.

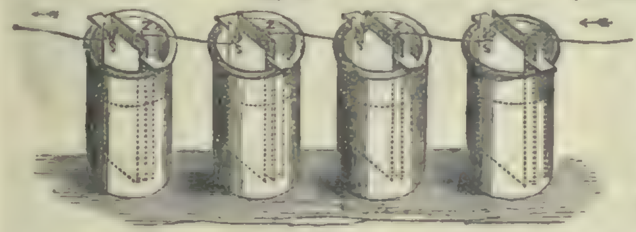


Fig. 88.

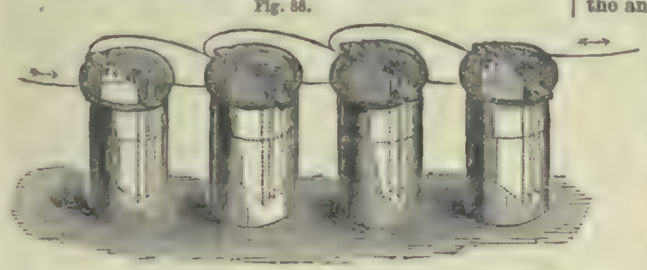

Fig. 89.

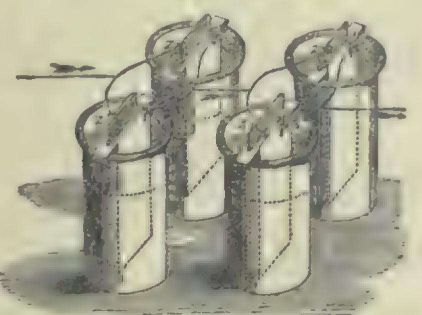


189. *Regulating the Quantity of Deposited Metal.*—The quantity of metal dissolved and deposited in the vat, is in direct proportion to the quantity of zinc dissolved and acid consumed in each alternation of the battery. With a perfect depositing liquid, good battery arrangements, and pure materials, for every equivalent of zinc dissolved in each alternation of the battery, an equivalent of metal is dissolved on one side, and an equivalent deposited on the other, in the depositing vessel. For instance—for every equivalent (32·6 parts) of zinc so dissolved, and 49 parts, or one equivalent, of oil of vitriol consumed in the battery, an equivalent (31·7 parts) of copper is deposited in the sulphate of copper solution, or an equivalent (108 parts) of silver in the cyanide silver plating liquid, and similar quantities of copper or silver dissolved at the anode. But in practical working, the materials are rarely or ever pure, or the arrangements perfect; the zinc nearly always contains a small proportion of other substances; the mercury contains tin or lead; and the sulphuric acid contains a little nitric acid. The acid liquid of the battery is often too strong: much acid liquid is frequently wasted, being thrown away before it is completely exhausted: the zinc plates have not been kept well amalgamated, or the silver well platinised, or the plates have been suffered to remain too long in the liquid when not in use. The metal of the anode is frequently impure also; occasionally some of the deposit is allowed to redissolve, in consequence of the battery power becoming low, and from not stirring the solution; in some solutions, a part of the battery strength is expended in evolving gas at the cathode; and, finally, the repeated operation of "scratching" removes some of the deposit. Allowing for all these and other unavoidable sources of loss in practical working, about one pound only of copper can be deposited in the ordinary sulphate solution, by the consumption of from one-and-a-quarter to one-and-a-half pounds of zinc, and an equivalent quantity of acid, in each alternation of the battery. To increase the quantity of metal deposited in a given period of time, the battery plates should be sunk deeper in their liquids.

190. *Regulation of the Quality of the Deposit.*—The quality of the deposited metal, *i.e.*, its degree of cohesion, hardness, flexibility, &c., depends upon the intensity of the current. As a general rule, the greater the intensity and the smaller the quantity of the current, the harder and brighter is the deposited metal; and the greater the quantity and the smaller the intensity, the less coherent and the softer it is. To obtain a very hard, bright, and crystalline deposit, we should use a current of small quantity and high intensity; and to obtain a soft black powder deposit, we should employ large quantity and low intensity; the combination of moderate quantity and moderate intensity, produces a coherent reguline deposit, possessing all the ordinary characteristics of the particular metal. These results can only be obtained with a good depositing liquid, and with metals, such as copper, silver, gold, &c., which are known to exist in a tough reguline state; and not with those—such as bismuth or antimony, crystalline metals—which do not exist in that state.

---

* See *ante*, p. 137.

191. If we are producing a reguline deposit, with a one-cell arrangement, in a good depositing liquid, with electrodes of the same size as the immersed portion of the battery plates, and it is wished to change the deposit to a soft black powder, the plates of the battery must be immersed considerably deeper in the liquid, and a very much larger dissolving plate in the vat used. If we wish to change the deposit to a crystalline one, several more pairs of battery should be put on, connected intensity-fashion, and the plates must be immersed to an exceedingly small depth in their liquids, and a very small anode employed. These results have a direct reference to the size of the receiving surface: for if, with any given battery and anode, we are producing a black powder deposit upon a very small article, a larger article would receive a reguline deposit, and a much larger one would have thrown down on it a deposit bordering upon the crystalline state. Thus it will be perceived that the black powder deposit is a result of too rapid, and the crystalline one of too slow action.

192. *Spread of Deposit.*—If we wish to make a deposit spread rapidly over a metal of inferior conductibility, such as a long iron rod, we must use a current of high intensity and rather small quantity; this will drive it over the surface without causing it to become soft or non-coherent. The action of such a current appears to consist in conferring upon the particles a kind of polarity, a power of grouping themselves into separate warty nodules or crystals, each of which, as it becomes larger, appears to powerfully repel its neighbour, and thus causes the metal to spread rapidly; when this action is continued to a considerable thickness of deposit, especially in cold weather, the metal is exceedingly hard, and easily broken into a number of distinct grains or nodules, which are in the form of warty lumps with rounded edges. When the action has been rather too quick, or the liquid not sufficiently cold, and composed of more or less perfect crystals, with edges sometimes beautifully defined, or when the action has been very slow, and the liquid very cold and undisturbed, the same occurs. With the intensity of one hundred pairs of Smee's battery, acting for a long period of time in cold weather, and the quantity of the current kept down to the lowest possible degree, we have seen a tough deposit of zinc spread over several square inches of clean gutta-percha; and in depositing copper with a current of rather high intensity, and small quantity, upon blackleaded gutta-percha medallions, we have repeatedly observed, that where there was a sunk boundary line near the edge, the deposit remained quite thin, as if powerfully repelled, whilst on each side of the line it was very thick, and on the outside edge, accumulated in large warty masses, hard and distinctly separate, and containing as much metal as the whole of the medallion besides.

193. *Management of Batteries.*—The most suitable strength of liquid for filling the battery cells, consists of one measure of sulphuric acid and about twenty measures of water; a stronger liquid may be used, even to one part of acid to ten or twelve parts of water; but then the zinc plates require constant watching and frequent amalgamating, to prevent waste. If the acid liquid be very strong, and the electric action energetic, the zinc plates will require to be examined every day, to see that there is no local action, *i.e.*, chemical action in particular places; and when gas is found to be freely rising from them, as well as from the silver or copper, or when any dull patches appear where the acid has acted too strongly upon them, they should be taken out and amalgamated. They should be frequently amalgamated when new; and afterwards, if much worked, they should be amalgamated every few days: when they become old they should be rarely amalgamated, because it very much weakens the power. When they become so thin as to fall to pieces on handling, new plates should be substituted, and the old should either be melted at as low a degree of heat as possible, to prevent loss of mercury, and cast into rods for Daniell's batteries; or be broken up, put in an iron retort, and the mercury distilled from them at a strong red heat into a vessel of water.

194. The zinc plates should be taken out of the liquid every evening, unless deposition is required to continue all night. After the battery has been at work a few days, a little more acid should be added, and the liquid stirred; and this should be done as often as the power gets low, until at length the liquid becomes thick and nearly saturated with zinc salt, which crystallises about the edges of the cells. It is then time to throw it away and put fresh, or it may be filtered, evaporated, and crystallised, and the resulting salt (sulphate of zinc) preserved for depositing purposes. If any of the silver or copper plates of the batteries become covered with a deposit of zinc whilst working, it shows that all the acid in that cell is exhausted, and that more should be added, or fresh liquid put in. This only happens in a Smee's battery, or in the old zinc and copper arrangement. The deposit of zinc may be easily and quickly removed by the addition of acid to that cell, by a fresh liquid, or by immersing the coated plate in dilute sulphuric acid as long as gas is evolved from it.

195. If copper plates are employed in the batteries, they should be heated red-hot all over every week or ten days, and quenched in water, and then dipped in "dipping liquid" (82), or in nitric acid; and if platinised silver plates are used, they should be re-platinised as often as they become light in colour, or their power becomes low, which will happen once in two or three months with constant working. The re-platinising greatly increases the power of the battery. Great care must be taken that the zincs never touch the silver or copper plates when wet, otherwise the mercury will get upon the latter, and much weaken the battery power; and the silver plates will drop to pieces if they are very thin.

196. *General Rules for Working Solutions.*—In working any depositing liquid—1st, avoid doing anything which will alter the chemical composition of the liquid, or even the proportions of its ingredients, except the water—that may be altered, in proportion, in most liquids without much inconvenience; 2nd, adapt your electric power to the liquid, rather than the liquid to the power, and regulate the deposit rather by alterations in the battery than by alterations in the depositing vessel, except as regards the distances of the electrodes or the temperature of the liquid—these may be altered with safety, and, sometimes, with convenience; and 3rd, as a general rule, let your dissolving metal, the anode, expose a larger immersed surface than the receiving article, the cathode.

197. *Position of Articles and Dissolving Plates.*—The best practical position for the dissolving plate is the vertical, the dissolving plate and the receiving article being suspended in the liquid facing each other, the latter being rather the lowest of the two, and both wholly immersed. The horizontal position, with the dissolving metal above, although the most philosophical arrangement, does not succeed in practical working, because the metal used for dissolving, is never quite pure (with copper, especially), and the impurities from it fall upon the surface of the receiving article beneath, and make it rough; in addition to this, the position of the article prevents our being able to examine it easily or remove it conveniently. If the article to be coated have a very irregular outline, either the dissolving plate should be bent somewhat to its form, so that the two may be nearly equi-distant at all parts; or the article should be often shifted in its position, so as to produce a nearly uniform thickness of deposit all over. The nearer the receiving article is to the dissolving plate, the more rapid is the deposit; and a large body of liquid deposits more rapidly and more evenly than a small one; large connecting wires are more favourable to quick deposits than small ones. The greatest thickness of deposit always takes place upon the most prominent places, *i.e.*, upon those parts nearest the dissolving metal.

198. *Motion of Articles in Vat.*—In some solutions—for instance, the double sulphite of silver and potash—if the current be too strong to produce a good deposit, motion of the articles will prevent it becoming bad. In some plating establishments, the articles in the vats are

kept in constant motion, gently swinging to and fro—the metal frame upon which they are suspended having four small wheels running upon four small inclined planes fixed upon the edges of the vat, which are kept in constant motion by steam or other available power.

199. *Temperature of Solution.*—Several solutions, such as the cyanide of copper and potassium, the cyanide of gold and potassium, &c., require to be kept hot, in order to make them conduct freely, and yield suitable metal; not that they cannot be worked cold, but that they work much better and quicker at a high temperature, which more than compensates for the expense of heating them.

200. *Protection of Depositing Liquids from Light.*—Some liquids, such as the double sulphite of silver and potash, and the hyposulphite of silver and potash, require to be protected as much as possible from the influence of light; and even the ordinary cyanide of silver liquid is better screened from an excess of this agent.

201. *Clean Connections necessary.*—In every case we must be very careful to observe that the circuit is complete, and that it is capable of conducting the current freely throughout; that the articles to be coated are conductors of electricity, or have been made so by any of the means already recommended; and that their surfaces, as well as all the ends of the wires, at their various points of contact, are perfectly clean.

202. *Management of Coppering Liquids.*—With the sulphate of copper solution (120) no particular management is required, beyond the general rules already laid down (196). It is not suitable for depositing direct upon zinc, tin, lead, iron, or steel. Articles formed of these metals are first coated with a thin layer of copper, in the cyanide of copper and potassium solution (120); then well washed, and transferred immediately to the sulphate solution, and the remainder of the required thickness of copper deposited upon it.

203. *Uses of Copper Deposition.*—Among the many uses to which the electro-deposition of copper has been applied, we may mention the following:—To make copper cells for Daniell's batteries; making copies of stereotype plates, engraved copper plates, and engraved rollers; coppering the surface of printing-type; coppering steel pens (patented); to protect iron and steel goods from rusting, coating telegraph wires, ship's bolts, &c.; to make copies of Daguerreotype pictures; to make coppered cloth; to coat glass chemical vessels; to coat and protect metal and plaster statues, busts, and sculptured works; to preserve the form of flowers, fruits, ferns, seaweed, insects, reptiles, &c.; to make medallions, busts, and various figures and ornaments in copper; it has also been applied in the arts of glyphography and electro-tint printing.

204. *Making Objects in Copper, Coppering, &c.*—To make a cell of Daniell's battery in copper, coat the inside of a glass jar or earthen jelly-pot with wax, resin, or stearine, by making the vessel hot; then either blacklead it thoroughly, or treat it with the phosphorus, silver, and gold solutions; or, what is more simple, coat it uniformly all over the inside with the phosphorus moulding composition (87), and then treat it with the gold and silver liquids. Make a connection by a fine copper wire with the lower part of the coating; fill the vessel nearly full of the sulphate of copper depositing solution (120), suspend in it a sheet of copper, and connect the sheet of copper and the fine copper wire with a small battery of one or two pairs. If, instead of the battery process, we adopt the single cell arrangement, containing dilute sulphuric acid and a piece of zinc, placing a porous cell in the sulphate solution, and connecting the fine copper wire with the piece of zinc; a deposit of copper will soon spread over the entire inside surface of the jar, when that has been previously prepared by the phosphorus method. Engraved steel plates are copied by stopping-off the back with copal varnish, allowing it to become perfectly dry. They are then immersed in the cyanide coppering liquid, and a thin film of copper is thrown down: after washing well, they are at once immersed in the sulphate of copper solution, and the required thickness of copper is deposited; this will require from 24 to 48 hours. The surface of the steel should be previously prepared for a non-adhesive deposit, otherwise the two metals cannot be separated.

205. *Copying Wood-cuts in Copper.*—For printing purposes, where a large number of impressions of a particular wood-cut is required, the plan of taking copies of the engraved wooden block in copper by the electro-process, and using those copies instead of the original block to print from, has been gradually extending itself for some years, and has now attained a considerable degree of importance; the vignette at the head of the title-page of the *Illustrated News*, the title-page of *Punch*, many of the large engravings in the *Illustrated News*, and even the illustrations of some of the penny periodicals, are regularly produced in this way. To copy an engraved wooden block, the engraved surface is first moistened with water, and firmly enclosed by a shallow frame; a thick piece of gutta-percha, more than sufficient to fill the enclosed space, and made quite soft by heat, is then laid upon it, commencing its contact at the centre of the engraving, and proceeding outwards, so as to exclude all air-bubbles; a plate of cold iron is then laid upon the gutta-percha, and the whole subjected to pressure, gentle at first, but increased to a high degree as the substance cools. The block and copy are then separated, and the figured surface of the gutta-percha (with connecting and guiding-wires previously attached) is treated in the usual manner with blacklead or with the phosphorus, silver, and gold solutions; copper is then deposited upon it in a solution of sulphate of copper, until a moderate thickness of deposit is obtained, which will occupy at least twelve or eighteen hours; when sufficiently thick the deposit is removed, its back made rigid by a layer of solder or type-metal (the surface being previously moistened with a solution of chloride of zinc to make the solder adhere), the back is planed flat, and mounted upon a block of wood to the height of the type. In London this process is carried on upon a large scale, some of the copies being upwards of two feet square. Engravings upon steel are copied in an exactly similar manner to those upon wood.

We have recently tried some experiments with a view of making the deposit of copper upon gutta-percha and marine glue spread more rapidly than it does, by preparing the surface with blacklead; it being a matter of some importance, in copying wood engravings for periodicals of such large circulation as the *Illustrated News*, that the time occupied in the process be reduced. Our experiments have succeeded to some extent, and we give the following results of them for the benefit of the printing trade.

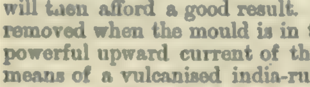
After having formed a reverse copy, in gutta-percha and marine glue, of the engraved wooden block, and affixed the conducting wires to it, take a mixture of one measure of spirit varnish, and either four or five measures of vegetable naphtha, and apply it very sparingly in a thin layer, by a soft camel's-hair brush, over the whole surface of the mould where the deposit is desired to be spread. Whilst the surface is still wet, cover it with a mixture of three parts of yellow and one part of white bronze powder, and bring the powder in thorough contact with the whole of the moistened surface, by striking it all over with a dry, soft brush; then gently brush off all the superfluous powder. The bronzed mould may now be immersed in the ordinary sulphate of copper solution, and the following actions will occur:—The particles of white bronze powder being composed almost wholly of tin, and those of yellow bronze containing much copper, those of tin will dissolve and coat themselves with copper by the simple immersion process (4), and those of brass or copper (the yellow ones) will become coated by their contact with those of tin (Two Metals and One Liquid Process, 7), and thus a thin deposit of copper will almost instantaneously spread all over the bronzed surface. This effect will of course take place without connecting the mould with the battery; but they may be immediately connected together, and a deposit will spread almost instantaneously over the whole of the bronzed surface by the ordinary battery process, through the medium of the bronze and the thin deposit already mentioned, which may be continued to any required thickness in the usual way. In our earlier experiments with this method, yellow bronze alone was used, which did not reduce the copper by simple immersion; but even then, medallions were repeatedly covered with a deposit of copper in from two to five minutes, which would occupy from twenty to forty-five minutes when prepared by blacklead in the usual manner. The addition of white or tin bronze causes the deposit to spread as rapidly as when the surface is prepared by the phosphorus solution, but without the disadvantage which occurs in using the latter, of making the deposited metal brittle. The effect of using white bronze alone was not so satisfactory.

The surface of the copper copy so obtained is bright and clean, and the character of the deposited metal is good, but the surface obtained is hardly so smooth and fine as that obtained with blacklead; the difference, however, is very slight, and it is sufficiently smooth for all ordinary purposes, and for the object sought, if care be taken to blow off or otherwise remove all superfluous bronze powder before immersing the mould in the vat. We hope that those who may have the opportunity will try it upon a larger scale.

206. *Copying Set-up Type in Copper.*—The process of electrotyping has also been gradually encroaching upon that of stereotyping, and has, we are informed, almost superseded that process in America. The plan adopted is similar to that of copying wood-cuts—viz., to lay a sheet of softened gutta-percha upon the surface of the page of type, and subject it to increasing pressure until it is cold; the gutta-percha copy is then removed, and treated as in copying wood engravings. It would be advisable to try a somewhat softer material for this purpose, such as the mixture of gutta-percha and marine glue, which we have recommended (85). This material takes a sharper and smoother impression than gutta-percha alone, and the deposit spreads over it more rapidly; and, being softer, it enters more freely and with less pressure between the fine lines of the letters, and still is not sufficiently soft to penetrate the minute crevices between the body of the types. If a solution of grape-sugar (as used in Drayton's patent process for silvering glass), aldehyde, or other reducing agent, were substituted for the phosphorus solution, for reducing the silver upon the surface of the mould, it would be an advantage, as, besides the dangerous character of the phosphorus, it has an offensive odour, and the copper deposited upon surfaces prepared by it, moreover, is invariably brittle.

The mould may also be prepared for a deposit by blackleading; it will require a first-rate quality of blacklead, and prolonged and attentive brushing, but will then afford a good result. The air-bubbles may be removed when the mould is in the liquid, by directing a powerful upward current of the liquid against them by means of a vulcanised india-rubber bladder, with a long and curved glass tube having a fine orifice (Fig. 90) attached to it; but the liquid should be free from sediment.

Fig. 90.



The advantages of electrotyping over stereotyping are numerous; the metal is harder, takes a sharper impression of the mould, and delivers the ink much more readily than type metal, besides being a cleaner process; it also takes up less ink, and consequently the printed pages dry more quickly. Both wood-cuts and letter-press have also been copied in plaster of Paris, and the deposit of copper formed upon that; but this material is much inferior to gutta-percha for the process. Messrs. Bradbury and Evans are considered the most successful manipulators in this branch of electro-deposition, and their apparatus the most perfect of its kind. In this establishment the temperature of the room is carefully attended to, and the vessels containing the solutions have glass covers. The result of this careful manipulation has been, that, in some instances, successful deposits of large *Illustrated News* engravings have been formed and taken off in eight hours; this can only have been effected by the most perfect blackleading, keeping the solution in excellent condition, and working with the maximum of battery power. Gutta-percha and marine glue is well worthy of a trial, and the use of bitumen with gutta-percha is also a good idea; the marine glue would be better, because it is tougher.

Iron and steel wire may be coated with an adhesive deposit of copper, by first immersing them, with their surfaces perfectly clean, in the cyanide coppering liquid, and completing the deposit in the ordinary sulphate solution. The coils should be kept separate from each other in the liquid by suspending them upon a horizontal brass rod, turning it occasionally to cause a uniform deposit. Iron screws and nails may be treated in a similar manner, except that they should be contained in a wicker basket, and shook about occasionally to produce a uniform deposit.

207. *Copying Daguerreotype Pictures in Copper.*—The most interesting and beautiful application of the deposition of copper, and, at the same time, one of the easiest to be effected, is that of copying Daguerreotype pictures. First solder a wire to the back of the plate near the edge; paint over the back and edges, and allow it to dry; hang it in a clean sulphate of copper solution, which is perfectly free from dust or grease on its surface; and, in the course of twenty or thirty hours, if about two cells of small Smee's batteries have been used, the deposit will be sufficiently thick to be removed; it should then be taken out, well washed, wiped perfectly dry, and a narrow strip be cut off its edges with a strong pair of scissors; the two may then be easily separated by inserting the point of a knife, or the end of a thin wedge of hard wood, between them at the edges. If the process have been carefully managed, and the original picture be a strong one, a most beautiful and vivid copy will be obtained; and if the picture be not only a strong one, but has also been well fixed by Fizeau's process, a number of successive copies may be taken from it; but their intensity, as well as that of the original, appears to diminish in each succeeding trial. With a vivid original picture, clear solution, very regular and undisturbed action of the battery, and a fine deposit, we have observed a most strange phenomenon—viz., the picture has not entirely disappeared, even in twenty hours, although the coating of copper has constantly increased in thickness; the image has penetrated quite through the deposited metal, and appeared upon the back, even upon deposits as thick as an address-card. In some cases the figure was optically positive, and in others negative.

208. *Coating Plaster Models, Flowers, and Clay Figures with Copper.*—Busts and other similar objects may be coated by saturating them with linseed oil, then well blackleading, or treating them with the phosphorus, silver, and gold solutions, and attaching a number of guiding-wires, connected with all the most hollow and distant parts. The object is then to be immersed in a sulphate of copper solution containing no free acid, and just sufficient copper is to be deposited upon them by the battery process to protect them, but not to obliterate the fine lines or features. Flowers, fruits, ferns, seaweed, insects, &c., may be prepared by the phosphorus, silver, and gold liquids, and the copper deposited upon them, either by the single cell or battery process, in a neutral sulphate of copper solution.

209. *Coppering Cloth.*—To copper cloth, first stretch it upon a sheet of copper slightly curved, so that it may be in close contact with the metal all over; then varnish the back or hollow side of the copper, and deposit on the opposite side, by the battery process, from a sulphate solution not containing much free acid, until the meshes of the cloth are quite filled with copper, and the metal and cloth firmly united together; the deposit may then be removed and well washed: the original sheet of copper should of course be properly prepared for a non-adhesive deposit. Mr. J. Schottlaender took out a

patent, December 8th, 1843, for depositing either plain or figured copy upon felted fabrics. He passes the cloth under either a plain or an engraved copper roller, horizontally immersed in a sulphate of copper solution not containing much free acid, and a deposit takes place upon the roller as it slowly revolves; the meshes of the cloth are thus filled with metal, and the design of the roller copied upon it. The coppered cloth is slowly rolled off, and passed through a second and closely contiguous vessel filled with clean water; the roller is properly prepared for a non-adhesive deposit.

210. *Etching Copper.*—In etching a copper plate by galvanism, we first solder a wire on the back, then varnish the back, and cover the front with a thin layer of engravers' etching-ground; draw the design upon the front surface with an etching-needle, cutting through this material to the clean surface of the copper. Having completed the etching, hang the plate as an anode in the ordinary sulphate of copper solution, opposite a suitable cathode of brass or copper. The current of electricity, in passing out of the engraved lines into the liquid, causes the copper in them to dissolve, and thus etches the design in the plate. The different gradations of light and shade are produced by suspending cathodes of different forms and sizes opposite the plate to be etched, in different positions and at different distances from it, thus causing the etching to be of different depths in different parts, the deepest action being always at the parts of the electrodes nearest together.

211. *Glyphography.*—This art consists in varnishing the back of a flat and smooth copper plate, laying first a thin coating of white etching-ground upon its front side, and then a layer of black etching-ground upon that; engraving the design upon the coating with different engraving-tools; then blackleading the whole of the engraved surface, and depositing a thick sheet of copper upon it in a sulphate solution by the battery process. The deposited plate is then removed, its defects corrected, and fixed upon a block of wood in the same manner as a stereotype plate, ready for printing by the ordinary hand-press. This process has been patented, and the patent is worked by Mr. Hawkins, Hatton Garden.

212. *Management of Silver Solutions.*—Silver plating liquids require much more care and attention than the sulphate of copper solution. Articles formed of zinc, iron, or steel, require to be coated with a thin film of copper in the cyanide of copper liquid, before being immersed in the cyanide of silver solution. Those formed of Britannia metal, tin, or pewter, are taken direct from the hot potash liquid without rinsing in water, and immersed a short time in a cyanide of silver solution containing considerable supplies of free cyanide. A large anode is used, and a current of considerable intensity from a strong battery passed through for several minutes, until the articles receive a thin deposit of silver; they are then transferred to the ordinary vat to receive the full amount of deposit. Those of lead are first scraped, or otherwise made quite clean and bright by mechanical means, and then treated in the same manner as those of Britannia metal. Articles of copper, brass, or German silver, after being properly cleansed, are dipped into the solution of nitrate of mercury (84), or of cyanide of mercury and potassium (84), then rinsed in a vessel of water, and immediately suspended in the depositing vat. The preparation of those articles by immersion in a bath of cyanide of mercury, was patented by Dr. H. B. Leeson, June 4th, 1842, and is in use by the electroplaters of Birmingham. If they are immersed without this preparation, the deposited silver will not always adhere firmly.

213. *Peculiarities in Practical Silver Deposition.*—Peculiar phenomena often occur in the electro-deposition of silver, not only upon different metals, but also upon the same metals in different forms or in different conditions of surface. For instance—

1st. If two perfectly similar pieces of thin sheet brass are taken (except that one is perforated all over with small holes), and both be simultaneously immersed in the same solution to be silvered, and with the same battery power applied to each, the latter, although its amount of surface is reduced by the perforations, will become coated with silver much more slowly than the former.

2nd. If a wire-gauze cylinder of a Davy lamp be suspended side by side with a piece of thin tubing of the same metal and of the same dimensions, the latter will become coated much more rapidly than the former.

3rd. If two pieces of the same metal—iron for instance—be immersed, to be silvered, in the ordinary cyanide solution, or to be coppered in the hot cyanide of copper and potassium liquid, each containing exactly the same amount of surface to be coated, but one being in the form of a thin sheet, and the other in that of a thick plate or solid block of metal, the former will become coated much more rapidly than the latter.

4th. The edges and points of articles, whilst being plated, exhibit a greater tendency to a crystalline deposit than the flat parts, and this tendency is sometimes manifested in depositing silver upon table-knives and forks. It is the knowledge of these and many other peculiarities of different metals and articles met with in practical working, and of the means of overcoming their attendant difficulties, which constitutes one of the chief differences between the practical operator and the scientific man.

214. *Management of "Bright Solution."*—A bright solution is much more difficult to manage than the ordinary silvering liquid; if it be not worked constantly and in a uniform manner, it will lose its power of yielding bright metal. If any of the articles which are being plated in it are disturbed, or removed from the liquid and replaced, that one will not now receive a bright deposit; and the disturbance of the liquid, by removing it, will oftentimes cause all the neighbouring articles to lose their brightness. If too much "brightening liquid" (144) be added, the solution will be considerably injured: many silver solutions have been irretrievably damaged in this way. A bright solution requires a battery current of large quantity and low intensity to work it, and the dissolving plates in it are generally of a darker colour than those in the ordinary silvering liquid; the silver deposited from it is much harder than that deposited from the ordinary plating solution, and has very much the appearance of fused metal; the bright appearance commences at the upper part of the articles, and travels downwards; it soon after commences also at their lower extremities and travels upwards, until the bright portions meet each other. If there are very small holes in the surface of the articles, dull streaks appear above them.

215. *Adding Cyanide of Potassium to Plating Liquids.*—It is necessary to add a little cyanide of potassium occasionally to every cyanide of silver plating liquid, probably because the solutions absorb carbonic acid from the atmosphere, which converts some of the cyanide of potassium into carbonate of potash, and sets hydrocyanic acid gas free. A further portion of the potassium salt may also be decomposed by some means, with formation and escape of ammonia; the necessity of adding a little fresh cyanide is indicated when the dissolving plate begins to change from its ordinary pure white appearance to a dull yellowish-gray colour; it is best added in the evening after plating—about half-an-hour before stirring the solution.

216. If the solution be too strong, *i.e.*, if it contain insufficient water, but has silver and cyanide of potassium in their proper relative proportions, it conducts freely, deposits rapidly, and gives a rich deposit of a fine silky lustre; but it is more difficult to manage than a weaker liquid, especially in hot weather, because, from the less mobility of its particles, it is very apt to settle, by working, into strata of different densities—its upper part becoming exhausted of silver and full of free cyanide, and its lower part becoming nearly saturated with that metal, and destitute of free cyanide; the consequence of this is, that the upper parts of the dissolving plates waste rapidly, whilst the upper parts of the article receive either very little deposit, or one of a

bad quality, being gray, brown, or yellowish, sometimes of a lilac hue, and generally in dull streaky vertical lines: all these evils may be mitigated by stirring the solution well every night after having finished plating, or it may be entirely prevented by diluting the liquid with water to a proper extent, stirring it every evening, and working it uniformly. All silvering and other depositing liquids exhibit this tendency to settle into strata in working, especially if worked rapidly; but the most dilute ones show it in the least degree.

If the solution be deficient in water, and contain a great excess of free cyanide, the foregoing evils are all greatly aggravated. In hot weather it becomes very unmanageable, and the vapours of ammonia and hydrocyanic acid arising from it are quite overpowering. In this case, the best way to improve it is to add cyanide of silver and water in sufficient quantities to make it of a good composition, keep it in a cool place, stir it daily, and work it constantly in a uniform and careful manner. New solutions, or old ones which have been injured, often improve by daily stirring, with regular and judicious working. An excess of cyanide of potassium is indicated when the dissolving plates are very strongly acted upon, and the deposit is at the same time either very sparing or of a bad colour.

If the solution be too weak, *i.e.*, if it contain too much water, it conducts sparingly, deposits slowly, and the deposit has a dead-white appearance. This may be easily remedied by adding cyanide of silver and cyanide of potassium to it in proper proportions, and working it uniformly a few days with daily stirring.

217. *Washing, Drying, and Ornamenting Silver-plated Articles.*—Articles that have been plated with silver are always washed in a running stream of water until every trace of the depositing liquid is removed from them; they are then immersed in hot, dry sawdust, moved about in it, and gently rubbed with it until they are perfectly dry. After drying, they are, if necessary, weighed, to ascertain how much silver has been put upon them; then "scratched" (80), and finally finished by burnishing, polishing, &c.

Sometimes, for the purpose of ornament, portions of their surface are "oxidised." This is done by applying a hot solution of bichloride of platina (167) to them, and allowing it to dry. The more platina the solution contains, and the hotter it is, the deeper black does it produce; or it may be effected by the application of the solution of "liver of sulphur." To produce a brownish colour, apply a solution of equal weights of sulphate of copper and sal-ammoniac in vinegar; and to produce a "dead" appearance, like frosted silver, deposit a mere trace of copper upon it in a copper solution, then well wash it, and deposit a very thin layer of silver upon this. In each of these cases the parts which are to remain bright must be stopped-off with varnish.

218. *"Stripping" Silver from Copper and Copper from Silver.*—Occasionally the electro-plater has sent to him, to be replated, old worn-out articles formed of "Sheffield plate," in which the outer layer of silver has been worn away, and portions of the copper base beneath are exposed; these articles generally require to have the remaining portions of silver removed, in order to obtain a uniform surface to deposit upon. The removal of the silver is termed "stripping." To effect this, add a little nitrate of potash (saltpetre) to a quantity of strong oil of vitriol, and apply heat, until it is all dissolved; then immerse the articles in the hot liquid, and allow them to remain until all the silver is dissolved. If the action become slow, apply more heat or add more saltpetre; the copper will not be much acted upon if the articles are not allowed to remain in too long. A number of such articles are generally done together, and are afterwards washed, and prepared in the usual manner for receiving a deposit. The silver may be recovered from the liquid, in the form of chloride of silver, by diluting it with much water, then adding a solution of common salt to it as long as a precipitate is produced: the precipitate, when washed and dried, is chloride of silver. By fusing this with carbonate of potash, the metallic silver is obtained.

To remove copper from silver (which is but rarely required), boil it in dilute hydrochloric acid, or immerse it in a hot solution of perchloride of iron. The latter solution may be made by adding peroxide of iron (crocus, jeweller's rouge) to hydrochloric acid as long as it will dissolve; it will remove either tin, lead, or copper, from either gold or silver, without affecting those metals. A solution of chloride of zinc has been used for the same purpose. Copper may also be completely removed from silver or gold, by making it the anode in a sulphate of copper solution until all the copper is dissolved; the silver will remain unaffected, if the current employed be feeble and has not a greater intensity than one or two cells.

219. *Testing the Purity of Silver.*—M. Runge adopts the following method of testing the purity of silver:—He immerses the article in a mixture of 32 parts of water, 4 parts of sulphuric acid, and 3 parts of chromate of potash. If the metal be pure, the immersed part quickly assumes a purple colour, which is less deep and lively in proportion to the amount of alloy contained in the silver. No other metal exhibits the same colour with this liquid.

220. *Testing the Amount of Silver and of Free Cyanide in Silver Solutions.*—To ascertain the amount of silver in a cyanide plating solution, add dilute sulphuric acid to a known quantity of the liquid as long as it produces a precipitate; wash and dry the precipitate, which is cyanide of silver—containing in every 134 parts, 108 parts of metallic silver. To test the amount of *free* cyanide of potassium, add a solution of crystallised nitrate of silver in distilled water to a known quantity of the plating liquid, as long as the precipitate formed continues to be redissolved, and note how much crystallised nitrate is used; every 175 parts expended indicate 130 parts of free cyanide, or about three parts of free cyanide to four parts of nitrate of silver.

221. *Management of Gilding Solutions.*—Cyanide gilding solution is generally kept in a glazed iron vessel, and heated either by a stove, or by gas jets beneath; or in a stoneware or glass pan immersed in boiling-water. On account of the general smallness of the articles to be gilded, the thinness of the deposit required, and the rapidity of the action in a hot liquid, the articles only need to be immersed in the solution for a few minutes; when a thicker deposit is required, they should be taken out several times, brushed, and reimmersed. Articles formed of iron or steel must be coated with a thin film of copper in the cyanide coppering liquid before gilding. The strength of battery used for gilding is generally about two cells of Smee's, of different sizes, according to the magnitude of the articles to be gilded. The loss of water by evaporation is generally made good by adding a little distilled water, after having finished gilding.

222. *Regulation of Colour in Electro-gilding.*—The general method now adopted for regulating the colour of electro-gilding is as follows:—After having prepared the solution, work it with a large copper anode until the deposited metal begins to deteriorate in colour; then replace the copper by a small gold anode. With the copper anode can be obtained a rich full colour, becoming deeper as the temperature of the liquid is higher; to produce a paler yellow, use a small gold anode with the liquid at a lower temperature.

223. *Recovery of Gold and Silver from Depositing Liquids.*—As both silver and gold solutions occasionally get out of working condition, and become quite unfit for use, it is very desirable that the operator should understand the chemical action of different substances upon them, and how to recover the metal. Those of silver generally get out of order, either from the addition of too much "brightening liquid;" from excess of cyanide of potassium, together with the heat of the weather, and injudicious management; from unsuccessful attempts to improve the condition of the liquid; from the accidental introduction of impurities; or from the liquid having been improperly made. Supposing it to be the usual

cyanide liquid, the silver may be recovered in the metallic state thus:—Evaporate the solution nearly to dryness; reduce the resulting salt to powder; mix it with its own weight of a mixture of one part of nitrate of potash and two parts of common salt; and roast the whole in an iron pan to dryness. Fuse the dried mixture at a bright red heat in an earthen crucible, until the silver collects at the bottom of the vessel in a melted state; then pour it slowly into a large quantity of water. The resulting granules of silver should not be used in making a new plating liquid, because they generally contain copper derived from the articles suspended in the plating solution (see 151), but should be exchanged at a silver refiner's for pure silver.

224. "The crystallised double cyanide of gold and potassium fuses and effervesces by heat, and is resolved into cyanogen gas, ammonia, and cyanide of potassium, if air be present; its complete decomposition requires a strong red heat. When it is strongly ignited, and mixed with an equal weight of carbonate of potash, a button of metallic gold is obtained. When heated with sulphuric acid, it gives off hydrocyanic acid gas, and, after ignition, leaves a mixture of gold and sulphate of potash. Iodine sets free cyanogen gas, forms iodide of potassium, and throws down the cyanide of gold. The aqueous solution of cyanide of gold and potassium gilding liquid, when mixed with sulphuric, hydrochloric, or nitric acid, slowly deposits cyanide of gold; and, when boiled with hydrochloric acid, it is completely resolved into cyanide of gold and chloride of potassium. Similar effects are produced by sulphuric or nitric acid, and even by oxalic, tartaric, and acetic acid."

225. *Extraction of Gold and Silver from Exhausted Solutions.*—"To obtain the remaining gold from gilding solutions which have become inactive, they should be evaporated to dryness, the residue finely powdered, and intimately mixed with an equal weight of litharge, fused at a strong red heat, and the lead extracted from the alloy button of gold and lead by warm nitric acid; the gold will then remain as a loose yellowish-brown spongy mass."

226. The following extracts are from the works of Bœttger, J. Pr. Chem., 36, 169; Elsner, Redtel, Hessenberg, J. Pr. Chem., and other foreign writers:—"I have undertaken a series of researches upon this subject, and hasten to communicate the results to the public; but, before proceeding to the communication, I think it necessary to mention the results of the experiments upon which are based the methods given further on for extracting both the silver and the gold of old cyanide of potassium liquids.

227. "1st. If we add hydrochloric acid to a solution of silver in cyanide of potassium, until the liquid exhibits an acid reaction, we obtain a white precipitate of chloride of silver, which, when submitted to heat, melts into a yellow mass. If this were cyanide of silver, the application of a red heat would have left a regulus of silver. The addition of the hydrochloric acid precipitates all the silver present in the liquid in the form of chloride of silver.
